Host responses	5		

The mycosis caused by *Emmonsia* species is called adiaspiromycosis. The disease name is based on the cells found in tissue which have been termed adiaspores. Adiaspores are formed in vivo when inhaled conidia, which initially measure about 4 μm diameter, enlarge to form thick-walled spherule-like cells reaching 15–300 μm diameter. The size of the adiaspores is dependent upon the species involved, with those of *Emmonsia crescens* being larger than those of *Emmonsia parva* (Table 1). Although adiaspores of *Emmonsia* spp. may resemble the spherules containing endospores produced by *Coccidioides immitis* (Table 1), adiaspores do not form internal spores, nor do they further replicate. Infections usually occur in animals, and many species of burrowing animals, including rodents, small carnivores, insectivores, marsupials, and edentates, throughout the world, have been found to be infected. Adiaspiromycosis in humans usually involves the lung, is often self-limited, benign and asymptomatic, with rare cases progressing to a fatal outcome. Diagnosis is based most commonly on radiological and histopathological findings. Available evidence suggests that *Emmonsia* spp. are weak pathogens and that pulmonary impairment and elicitation of symptoms is dependent upon the number of conidia inhaled. *Emmonsia* spp. are only rarely reported as the cause of extrapulmonary infection; one such report involved *Emmonsia pasteuriana*, described as a new pathogen in 1998.

ETIOLOGIC AGENTS

The genus *Emmonsia* currently includes three species: *E. parva* (Emmons & Ashburn), Ciferri and Montemartini (1959), *E. crescens* Emmons and Jellison (1960), and *E. pasteuriana* Drouhet, Gueho & Gori (Drouhet et al. 1998). The taxonomic history of *Emmonsia* spp. has been complicated. Mycologists have disagreed about the appropriate genus for the species, and about their relationship to the dimorphic pathogens. Recently, classical mating experiments and DNA sequence comparisons have provided evidence to confirm that the closest relative to *Emmonsia* spp. is *Blastomyces dermatitidis* Gilchrist & Stokes. Molecular techniques also helped to classify an *Emmonsia*-like isolate that differed in producing yeast-like cells, rather than adiaspores, in vivo. *E. pasteuriana* is known thus far only from a single case of disseminated cutaneous infection in a patient with the acquired immunodeficiency syndrome (AIDS). Other species formerly assigned to *Emmonsia*, i.e. *Emmonsia brasiliensis* and *Emmonsia ciferrina*, have been reclassified (Padhye and Carmichael 1968).

ETYMOLOGY

The term adiaspore comes from the Greek verb *speirein* (*a* – negative, *dia* – through, *speirein* – to scatter or

Table 1 *Comparison of* Emmonsia *spp.*[a] *with* Blastomyces dermatitidis, Paracoccidioides brasiliensis, Histoplasma capsulatum, *and* Coccidioides immitis

	Ecology and distribution	Mycelial form	Teleomorph	Parasitic form in vivo	Confirmatory tests	Figure showing morphology in vitro and in vivo
Emmonsia crescens	Many animal hosts (about 120 species of rodents, lagomorphs, carnivores, insectivores, herbivores, marsupials), rarely soil. Worldwide except Africa, Australia	Narrow hyphae forming solitary sessile conidia and 1–3 conidia at the ends of narrow, often slightly swollen stalks. Conidia subglobose, often slightly broader than long, 2.5–4 μm long and 3–5 μm wide, smooth to finely roughened	*Ajellomyces crescens*	Oval or globose adiaspores, 50–500 μm, commonly 300 μm in diameter, walls 10–70 μm thick	Maximum growth temperature 37°C (lower for some strains), forming adiaspores measuring 20–140 μm. Exoantigen tests may show nonspecific precipitin lines against *B. dermatitidis* and *H. capsulatum* antisera	Emmonsia parva	Few animal hosts (about 21 species of rodents, lagomorphs, carnivores, and marsupials), rarely soil. Geographically restricted (parts of USA, Kenya, Europe, Australia)	Narrow hyphae forming solitary sessile conidia and 1–3 conidia at the ends of narrow, often slightly swollen stalks. Conidia subglobose, often slightly broader than long, 2.5–4 μm long and 3–5 μm wide, smooth to finely roughened	Not known; relationship to *Ajellomyces* inferred	Oval or globose adiaspores, 10–40 μm in diameter, walls thin	Maximum growth temperature 40°C, forming adiaspores measuring 8–20 μm diameter. Exoantigen tests may show nonspecific precipitin lines against *B. dermatitidis* and *H. capsulatum* antisera	Similar to *E. crescens*, but smaller adiaspores
Emmonsia pasteuriana	Known only from human host in Italy	Narrow hyphae forming solitary sessile conidia and 1–3 (sometimes up to 8) conidia at the ends of narrow stalks, often swollen distally to form a vesicle-like structure. Conidia subglobose to oval, often slightly broader than long, 2–5.5 μm long by 2–3.5 μm. Conidia subglobose, smooth to finely roughened or tuberculate	Not known; relationship to *Ajellomyces* inferred	Small and large yeast cells; small cells oval to pyriform (2–4 μm), often intracellular; occasionally larger, thick-walled (8–15 μm); all with narrow-based buds; budding mostly unipolar, sometimes bipolar	Converts to yeast form at 37°C on enriched media; no adiaspores formed	Blastomyces dermatitidis	River and forest soil, beaver dams, habitat poorly known. North America in areas along Mississippi and Ohio River valleys, eastern and central Canada, rarely Africa, Asia and Middle East	Narrow hyphae forming solitary sessile conidia and 1, uncommonly 2, conidia at the ends of narrow, usually unswollen stalks. Conidia mostly pyriform, 4–5 μm long and 3–4 μm wide	*Ajellomyces dermatitidis*	Large yeast cells, 10–12 μm in diameter, double contoured wall and single broad-based bud	Converts to yeast form at 37°C on enriched media; yeast cells large, thick-walled with broad-based buds. DNA probe and exoantigen test	Paracoccidioides brasiliensis	Rarely isolated from soils (coffee plantation, rain forest), armadillos, habitat considered to be forest areas of moderate climate, medium to high annual rainfall, in Central and South America	Narrow hyphae often remaining sterile; occasionally forming lateral or terminal pyriform conidia or intercalary arthroconidia that are slightly swollen (2–5.5 μm long and 2–3.5 μm wide)	Not known; relationship to *Ajellomyces* inferred	Thick-walled central cell up to 30 μm in diameter, bearing 1 to many daughter cells of varying size and joined to mother cell by narrow pedicel, occasionally occurring in short chains	Converts to yeast stage at 37°C on enriched media. DNA probe and exoantigen test	Histoplasma capsulatum var. *capsulatum*	Soil associated with dung of birds and bats. North America in areas along the Mississippi, Missouri, and Ohio River valleys of the USA, eastern Canada and Mexico, rarely in Central and South America, Asia and Europe	Narrow hyphae forming solitary sessile smooth or roughened, microconidia and tuberculate macroconidia at the ends of unswollen stalks. Microconidia pyriform, 4–5 μm long and 3–4 μm wide. Macroconidia broadly pyriform, 8–17 μm long and 8–13 μm wide or globose, 8–13 μm diameter	*Ajellomyces capsulatus*	Intracellular, rarely extracellular, small budding cells, 2–5 μm in diameter	Converts to yeast form at 37°C on enriched media; yeast cells small, oval, with narrow-based buds. DNA probe and exoantigen test	Coccidioides immitis	Soil of arid regions, animal burrows, has been found in mixed infections with *E. parva* in lungs of rodents and other burrowing animals. Geographically restricted to arid regions of southwest USA, Mexico, and parts of Central and South America	Hyphae forming alternate arthroconidia. Arthroconidia cylindrical 3–8 μm long and 3–5 μm wide	Not known; placement within the *Onygenaceae* inferred	Spherules 30–60 (–80) μm with walls 2 μm thick and containing endospores 2–5 μm in diameter	DNA probe and exoantigen test	
a) Modified from Sigler 1998, 2003 and based on data from Sigler 1996; figures copyright L. Sigler.

disperse), for the spherule which enlarges from the inhaled conidium (Emmons and Jellison 1960).

HISTORY

The first observation of infected animals and the suggestion of a fungal etiology are generally attributed to Kirschenblatt (Kirschenblatt 1939; Jellison 1969; Schwarz 1978; Rippon 1988) who, in 1939, applied the name *Rhinosporidium pulmonale* to the cyst-like bodies observed in lungs of several rodents. However, the name has not been used because it was not accompanied by the required Latin diagnosis or confirmed as applicable to a fungus by culture. The first valid name for the fungus dates from 1942. The earliest record of infection dates from a rodent specimen deposited in 1845 in a Swedish museum (Jellison 1969).

Infection in North America was first recorded in animals in Arizona. During the 1930s and 1940s, mycologists conducted surveys to define the natural habitats and endemic areas of the dimorphic systemic pathogens. These involved isolation of the fungi from soil, dung, or tissues of trapped birds and animals, and analysis of human exposure by measuring reactivity to antigens through skin tests. In 1942, Emmons reported that soil and desert rodents were natural reservoirs for *Coccidioides immitis* in regions of Arizona. Later that year, Emmons and Ashburn (1942) reported that some animals exhibited the presence of a second fungus forming spherule-like structures measuring up to 20 μm in diameter but lacking internal spores. Lungs of some animals contained both these cells and spherules of *C. immitis*. Thinking that their fungus had features typical of a zygomycete, Emmons and Ashburn (1942) named it *Haplosporangium parvum* and distinguished it from other species of the genus by the smaller size of the solitary sporangia. Some mycologists then considered *C. immitis* also to be a zygomycete bacause of the internal cleavage of the spherules into endospores (Emmons 1942; Baker et al. 1943). Congruences between *C. immitis* and *H. parvum*, including similarities in tissue morphologies, animals with dual infections, and skin test crossreactivity, led Emmons and Ashburn to speculate on a possible genetic relationship between them, even though *H. parvum* more closely resembled *B. dermatitidis* and *Histoplasma capsulatum* in cultural features.

Five years later, Dowding (1947) observed similar but much larger cells within lungs of rodents captured over a wide range in Alberta, Canada. The cells reached diameters of 300 μm and were often aggregated into pearly white nodules visible by gross examination. Cultures of the Alberta isolates grew poorly at 37°C, but conidia enlarged to form swollen cells as much as ten times greater in diameter and with walls up to 10 μm thick; on return to room temperature, these enlarged cells germinated to form hyphae. Dowding disagreed that *H. parvum* was most closely related to *C. immitis* because of the different type of conidia formed (i.e. arthroconidia in *C. immitis* versus solitary ones in *H. parvum*) and the lack of internal spores within spherules. Dowding also suggested that *H. parvum* was more closely related to *B. dermatitidis*, *H. capsulatum*, and *Paracoccidioides brasiliensis* and that these fungi, including *C. immitis*, formed a 'natural group.' She was the first to suggest a close biological relationship among the dimorphic pathogens. The placement of *H. parvum* in the zygomycete genus *Haplosporangium* was also challenged by Carmichael (1951). He suggested that the species was aligned most closely with *B. dermatitidis*; it formed conidia of the type that he later called 'aleuries' or aleurioconidia, and had affinities to members of the ascomycete family *Gymnoascaceae* (Ascomycota) (Carmichael 1951, 1962).

Ciferri and Montemartini (1959) made the necessary transfer of *H. parvum* to a new hyphomycete genus *Emmonsia* with *E. parva* as the type species. Emmons and Jellison (1960) described *E. crescens* for morphologically similar isolates that formed larger cells in vivo, for which they coined the term 'adiaspore.' They distinguished *E. crescens* from *E. parva* by the larger multinucleate (rather than uninucleate) adiaspores and by the lower maximum growth temperature. However, mycologists have disagreed on whether these differences were sufficient to recognize distinct species or varieties, and on the most appropriate generic name for the agents of adiaspiromycosis. For example, Carmichael (1962) re-evaluated the genus *Chrysosporium* and included in it many fungi producing aleurioconidia, including *B. dermatitidis* and the species of *Emmonsia*. While some mycologists accepted his proposed name *Chrysosporium parvum* with two varieties, *C. parvum* var. *parvum* and *C. parvum* var. *crescens* (McGinnis 1980; Boisseau-Lebreuil 1981; Rippon 1988; McGinnis and Rinaldi 1995), others argued for use of the genus name *Emmonsia* with the varieties *E. parva* var. *parva* and *E. parva* var. *crescens* (von Arx 1973; van Oorschot 1980; Kwon-Chung and Bennett 1992).

Recent evidence confirms that *Emmonsia* is the appropriate name for the agents of adiaspiromycosis, that the taxa should be considered species rather than varieties, and that there is a close relationship between *Emmonsia* spp. and *B. dermatitidis*. *Emmonsia* spp. and *B. dermatitidis* could be accommodated in the same genus but have been retained in separate genera mainly due to the differences in their parasitic forms (i.e. adiaspores versus yeast cells) and the clinical syndromes that they elicit. That distinction becomes less clear with the finding that the recently described *E. pasteuriana* demonstrates budding cells. Teleomorphs (meiotic or sexual stages) of *E. crescens* and *B. dermatitidis* are in the ascomycete genus *Ajellomyces*, as is that of *H. capsulatum*. The genus *Ajellomyces* is currently classified in the order Onygenales of the Ascomycota. Anamorphs (mitosporic or asexual stages) of onygenalean fungi are

commonly aleurioconidia or arthroconidia that are released by fracture or dissolution of all or part of the supporting hyphal cell (Carmichael 1962; Sigler and Carmichael 1976; Sigler 1997, 2003). For further discussion on relationships between *Emmonsia* spp. and the dimorphic fungi, see section on Teleomorphs and relationships below.

EPIDEMIOLOGY

Ecology, distribution, and animal infection

Even though *E. parva* was discovered first, *E. crescens* appears to be the primary agent of adiaspiromycosis in both animals and humans. However, it is difficult to verify the species involved in some literature reports due to uncertainty caused by nomenclatural controversy. The species can be verified only when size of the adiaspores observed in tissues is given. *E. crescens* has been reported worldwide from rodents, insectivores, carnivores, lagomorphs, and marsupials. Approximately 118 animal hosts were identified in detailed records compiled up to the 1970s and sporadic cases of animal infection have been reported subsequently (Dvorák 1968; Jellison 1969; Doby et al. 1970; Dvorák et al. 1973). *E. parva* is geographically more restricted and associated with fewer animal hosts. It has been recorded from about 21 species of rodents, lagomorphs, carnivores, and marsupials in the USA, Kenya, (former) Czechoslovakia, the former Soviet Union, and Australia (Jellison 1969; Doby et al. 1970; Krivanec and Mason 1980; Mason and Gauhwin 1982). Factors affecting geographical distribution are largely unknown. In North America, *E. crescens*-infected animals have been recorded from 13 states and four Canadian provinces, whereas *E. parva*-infected animals have been found in Arizona, Texas, Montana, and Utah. The original Arizona survey revealed a high prevalence of *E. parva* infection (33 percent of 303 animals) (Emmons and Ashburn 1942), but a survey of almost 1 800 animals collected over several years in (former) Czechoslovakia yielded 260 infected animals, of which only four showed infection with *E. parva* (Krivanec 1977). *E. crescens* has been found in New Zealand in a marsupial introduced from Australia (Johnstone et al. 1993), but it appears to be absent in neighboring Australia (Connole 1990). There, *E. parva*-like adiaspores have been observed in wombats, but culture yielded atypical nonsporulating isolates (Krivanec and Mason 1980; Mason and Gauhwin 1982). There is some basis to suggest that species could be introduced through transport of infected animals (Peterson and Sigler 1998).

Similarly to *B. dermatitidis*, the habitat for *Emmonsia* spp. is not well known, but animals are presumed to acquire infection by inhalation exposure to conidia in soil of wooded areas. Long-term studies in the Czech Republic have revealed that the highest prevalence of infection (33 percent) occurs in rodents from wooded windbreaks separating cultivated fields, compared with rodents from the fields themselves or from small plots of deciduous woods (Hubálek et al. 1995). Infection is absent in rodents that do not build their nests in soil (Hubálek 1999). Carnivores may play a role in distributing the organism by liberating adiaspores trapped in the tissues of their prey (Krivanec et al. 1975b; Krivanec and Otcenášek 1977). Viable adiaspores of *E. crescens* survive passage through the digestive tracts of mice, birds, and carnivores (Krivanec et al. 1975a; Krivanec and Otcenášek 1977; Hejtmanek 1985), as evidenced by the isolation of the fungus from the dung of coyotes for which rodents are a major dietary constituent (Sigler and Flis 1998). There are only a few records of direct isolation from soil and inanimate materials including moldy straw and bird's nest, all from Alberta, Canada (Sigler and Flis 1998; Peterson and Sigler 1998). Indirect isolation from soil occurred on at least one occasion when an *E. parva*-like isolate was recovered following experimental inoculation of soil into mice during a search for *H. capsulatum* in Missouri (Menges and Habermann 1954; Jellison 1969). However, molecular analysis revealed that the Missouri isolate is genetically distinct (Peterson and Sigler 1998).

In addition to habitat, factors affecting prevalence of infection are species and age of animal, season, geographical area, and altitude (Doby et al. 1971; Hubálek et al. 1995, 1998; Hubálek 1999). *E. crescens* infection is higher in mustelid carnivores, ranging from 30 to 76 percent of animals, than in small rodents and insectivores (1–50 percent) and large carnivores (<1 percent) (Doby et al. 1971; Krivanec et al. 1975a, b; Krivanec and Otcenášek 1977); however, the numbers of carnivores surveyed have been small. An 11-year survey of 10 081 small mammals from the Czech Republic found adiaspiromycosis in 13 percent of animals and a higher prevalence in rodents (13 percent of juveniles; 20 percent of adults) than in insectivores (2 percent of juveniles; 4 percent of adults) (Hubálek 1999). Infection is higher in adult rodents than in juveniles, but there is no difference in infection rates between adults according to sex (Hubálek et al. 1995). Dvorák et al. (1967, 1969) found seasonal variation with the highest incidence in spring. Hubálek et al. (1993) found the highest incidence in spring for voles and in winter for mice, reflecting differences in the animals' digging and burrowing activities. They also suggested that the peak of fungal proliferation may occur in spring when mean soil temperature, 5 cm below the surface, ranges from 3.4 to 12.2°C.

There have been few reports of illness or death of animals naturally infected with *Emmonsia* spp., but severely emaciated animals have been found postmortem to be heavily infected (Jellison 1969; Simpson and Gavie-Widen 2000). Hubálek et al. (1995)

determined the mean intensity of infection of *E. crescens* as 177.2 adiaspores per juvenile and 212.5 per adult rodent, with the number of adiaspores ranging from one to 4 618, and adiaspore size varying between 46 and 451 μm (mean 239.4 μm in adults). Lung tissues of some of these animals showed adiaspores of two distinct sizes, suggesting that they had been reinfected. Rare reports concern domestic or farm animals including two dogs (Al-Doory et al. 1971; Koller et al. 1976), a goat (Koller and Helfer 1978), and a horse (Pusterla et al. 2002). Findings were incidental in the goat and one dog, but the horse and a second dog demonstrated advanced pulmonary infection. In the case of the dog, which also had degenerative arthritis, organisms were found only in the lung and lymph nodes at necropsy (Al-Doory et al. 1971). The isolated fungus was inoculated into mice intraperitoneally, resulting in pulmonary lesions and recovery of the same fungus in culture. These findings are more suggestive of blastomycosis, known to be common in dogs, but the cells in tissue were described as irregular in size and nonbudding.

Experimental infection has been induced in dogs, guinea pigs, mice, rabbits, rats, and sheep, but not birds, by inoculating conidial suspensions, mainly of *E. crescens*, via intranasal, intraperitoneal, subcutaneous, or intravenous routes (Jellison 1969). Intravenous inoculation induces adiaspore development in all soft tissues, especially in the liver, lungs, and spleen. Golden hamsters were found to be less susceptible than other animals to developing adiaspiromycosis (Boisseau-Lebreuil 1975), and infectivity as well as persistence of adiaspores was greater after subcutaneous inoculation with *E. crescens* isolates than with *E. parva* isolates (Carmichael 1951). Time since injection, the strain used, the resistance of the animal, and the inoculation route are factors generally affecting the development of the adiaspores (Carmichael 1951; Dvorák et al. 1973; Slais 1976; Boisseau-Lebreuil 1977). Enlargement of conidia to adiaspores reaching 50–100 μm occurs within 2 weeks of intraperitoneal inoculation with *E. crescens* (Dvorák et al. 1973; Krivanec et al. 1974; Hejtmanek 1985). Experimental infection was obtained for *E. pasteuriana* only in golden hamsters following intratesticular inoculation; other routes of inoculation in the hamster, mice, and guinea pigs were unable to induce infection (Drouhet et al. 1998; Drouhet and Huerre 1999).

Human adiaspiromycosis

The number of recorded human infections is low, with approximately 50 cases of pulmonary or disseminated adiaspiromycosis reported from Central and South America, Europe, USA, and North Africa (Kwon-Chung and Bennett 1992; England and Hochholzer 1993; Sigler 1998). As with animals, infection occurs following inhalation exposure to conidia. Eleven patients whose case histories were reviewed by England and Hochholzer (1993) were adult white males from Argentina, Brazil, Germany, Guatemala, Spain, and the USA. Four of these individuals may have acquired the infection following inhalation of dust through farming, woodworking, or bird-handling activities. Eighteen cases of infection have occurred in Brazil in adult males between the ages of 26 and 62 (Barbas Filho et al. 1990; de Almeida Barbosa et al. 1997; Martins et al. 1997; dos Santos et al. 1997; Moraes et al. 2001). Three of these patients developed acute pulmonary infection following cleaning or renovation of buildings or the handling of rodent and bat carcasses or nesting material (Barbas Filho et al. 1990; de Almeida Barbosa et al. 1997). Soil dust from a garden shop was thought to have been the source of exposure for a 2-year-old Finnish girl (Nuorva et al. 1997). Of 14 case histories reviewed by Schwarz (1978) from the Czech Republic, France, Guatemala, Honduras, Russia, and Venezuela, four involved women and four involved boys aged 10 and 11 years. Most cases of adiaspiromycosis occur in non-AIDS patients. Underlying conditions have included tuberculosis, yellow fever, cancer of the bladder, diffuse lymphoma, chronic bronchitis, steroid-dependent emphysema, atherosclerosis, aortic atheroslcerotic aneurysm, and mycocardial infarction (Kodousek 1974; Schwarz 1978; Bambirra and Nogueira 1983; England and Hochholzer 1993; Moraes et al. 2001).

Pulmonary and disseminated infection have been reported in a few patients with AIDS (Echavarria et al. 1993; Gori et al. 1998; Turner et al. 1999). The histopathological presentations in these patients are dissimilar to classical adiaspiromycosis, suggesting that different *Emmonsia* spp. may be involved (Drouhet et al. 1998; Gori et al. 1998). The unusual features of these cases are discussed in the section on Infections in AIDS patients below.

HOST RESPONSES

Clinical manifestations of adiaspiromycosis

Adiaspiromycosis in humans generally involves the lungs and is often self-limited, benign, and asymptomatic. Functional disability and onset of symptoms is dependent upon the number of conidia inhaled (Barbas Filho et al. 1990). A heavy or repeated exposure may result in acute pulmonary disease with bilateral granulomatous lesions (de Almeida Barbosa et al. 1997). Patients are either asymptomatic or present with nonproductive cough, dyspnea on exertion, and low-grade fever; less common findings are hemoptysis, pain, chills, malaise, weight loss, night sweats, and crackles in the lungs (Barbas Filho et al. 1990; England and Hochholzer 1993;

de Almeida Barbosa et al. 1997). Almost all cases of human pulmonary adiaspiromycosis involve *E. crescens* (sometimes reported as *E. parva* var. *crescens*) (Schwarz 1978; Kwon-Chung and Bennett 1992; England and Hochholzer 1993; de Almeida Barbosa et al. 1997).

Diagnosis of infection is based most commonly on radiological (Figure 1) and histopathological findings without confirmation by culture. Diagnosis may be complicated by symptoms that mimic those of other fungal diseases, tuberculosis, sarcoidosis, Hodgkin's disease, or farmer's lung, or the co-occurrence with mycobacterial or other infections (England and Hochholzer 1993; de Almeida Barbosa et al. 1997). This may lead to failure to perform fungal culture, but even if adiaspiromycosis is suspected, fungal culture of sputum, bronchial washings, or bronchoalveolar lavage is often unsuccessful. Adiaspores may be discovered incidentally. In the first case of human infection, a single adiaspore was found in a nodule from a patient who had aspergillosis and cystic disease of the lung (Doby-Dubois et al. 1964). If numerous, adiaspores may be present in multiple granulomas involving both lungs (Schwarz 1978; England and Hochholzer 1993). Three forms of infection have been recognized (Kodousek et al. 1971; Vojtek et al. 1972; Schwarz 1978; England and Hochholzer 1993; de Almeida Barbosa 1997). These include:

1. a solitary or localized granuloma
2. a sporadically disseminated form
3. an acute, densely disseminated type with clinical symptoms.

The most prevalent findings in chest x-rays or computed tomography scans are diffuse bilateral reticulonodular infiltrates with areas of honeycombing (Barbas Filho et al. 1990; Peres et al. 1992; England and Hochholzer 1993). Most patients recover spontaneously or with antifungal therapy and/or prednisone, but in a few cases, the infection progresses to a fatal outcome (Peres et al. 1992; England and Hochholzer 1993; de Almeida Barbosa et al. 1997). Extrapulmonary infection is uncommon. Adiaspores of *E. crescens* were observed in two sections taken from an appendix of an 11-year-old boy with bronchitis (Kodousek 1974).

Infections in AIDS patients

Three patients with AIDS have been described recently as having infection caused by *Emmonsia* spp. In all cases, the fungus was grown in culture. This is in contrast to the failure to culture the fungus from non-AIDS patients with pulmonary adiaspiromycosis. Unusual findings in the case described by Echavarria et al. (1993) were dissemination involving bone, bone marrow, and lungs and extensive osteomyelitis. The fungus was identified as *E. parva* based on the smaller adiaspores, measuring between 25 and 35 μm in diameter. Although grown from pus, sputum, and bone marrow, the fungus was later lost to further investigation as to its relationship with other *Emmonsia* spp. Turner et al. (1999) described pulmonary adiaspiromycosis in a male with advanced HIV infection who was negative for both *Pneumocystis carinii* and mycobacterial infection. The fungus was grown from a bronchoalveolar lavage and a protected brush specimen and identified as *E. parva* by formation of adiaspores at 37°C. Fungal elements were reported to be present in the specimens, but their nature was not described nor were they illustrated in the report. The third case involved a female who developed disseminated cutaneous mycosis; histopathology revealed small yeast-like cells rather than adiaspores (Drouhet et al. 1998; Gori et al. 1998)

(Table 1). The fungus in culture demonstrated morphological features compatible with *Emmonsia*, but the isolate was found to be genetically distinct and described as a new species, *E. pasteuriana* (Drouhet et al. 1998).

Unconfirmed reports concerning *Emmonsia* species

Some reports which have been attributed to *Emmonsia* spp. are doubtful. In cases of skin (Thammayya and Sanyal 1973; Kamalam and Thambiah 1979) and corneal infection (Wagoner et al. 1999), the fungal elements in tissue are incompatible with those of *Emmonsia* spp. In two reports of deep infections (Stillwell et al. 1984; Warwick et al. 1991), one of endocarditis (Toshniwal et al. 1986), and one of sinusitis (Levy et al. 1991), the isolated organism was identified in each report only as *Chrysosporium* species; however, the discussions in each report implicate *E. parva* (as *Chrysosporium parvum*) and the reports have been cited by subsequent authors under that etiology. None of these cases can be confirmed as adiaspiromycosis. The fungus causing sinusitis described by Levy et al. (1991) is suspected to be the basidiomycete *Schizophyllum commune* (Sigler and Verweij 2003).

Histopathology

In histopathological examination of biopsy specimens, the adiaspores of *E. crescens* are generally found within granulomas, with each granuloma containing one or occasionally two adiaspores (Figure 2). In a severe infection, the pleural surface may appear grossly as grayish-white and thickened and marked by numerous discrete white nodules measuring up to 1 mm in size, with the intervening pulmonary tissue unchanged (Watts et al. 1975). Adiaspores appear as round or oval cells, ranging from 50 to 500 μm in diameter (commonly <300 μm), either lacking internal contents or appearing granular, and having walls between 10 and 70 μm thick (Kodousek 1974; Chandler et al. 1980; Hejtmanek 1985; England and Hochholzer 1993). The wall appears either trilaminar, staining positive with Gomori's methenamine silver, Gridley, and periodic acid–Schiff stains, or bilaminar when stained with hematoxylin and eosin (Watts et al. 1975). Adiaspores may be surrounded by a few macrophages and lymphocytes or by a granulomatous inflammatory reaction composed of epithelioid cells, macrophages, lymphocytes, plasma cells, scattered neutrophils, and fibrous tissue; eosinophils are uncommon (Albassam et al. 1986; England and Hochholzer 1993). Multinucleated giant cells may be seen in some granulomas. England and Hochholzer (1993) noted that patients with more acute infections of short duration (<2 months) presented with necrotic and suppurative granulomas, having adiaspores that averaged 100 μm and showed a paucity of T cells, B cells, and KP-1 macrophages on immunohistochemistry, whereas patients with infections of longer duration had non-necrotizing granulomas containing larger adiaspores (average diameter 155 μm) and demonstrated good immunoreactivity for T cells and KP-1-positive macrophages. Adiaspores in stages of collapse or being broken down by inflammatory cells can sometimes be observed (Albassam et al. 1986; England and Hochholzer 1993). The in vivo structures of other fungi, including the spherules of *C. immitis* or nonbudding yeast cells of *B. dermatitidis* (Table 1) and even *Curvularia* species in allergic bronchopulmonary disease, as well as parasites and plant cells, have been suggested as possible confounding factors in the differential diagnosis of adiaspiromycosis (England and Hochholzer 1993). Spherules of *C. immitis* are smaller on average (30–60 μm), have walls about 2 μm thick, and contain endospores 2–5 μm in diameter.

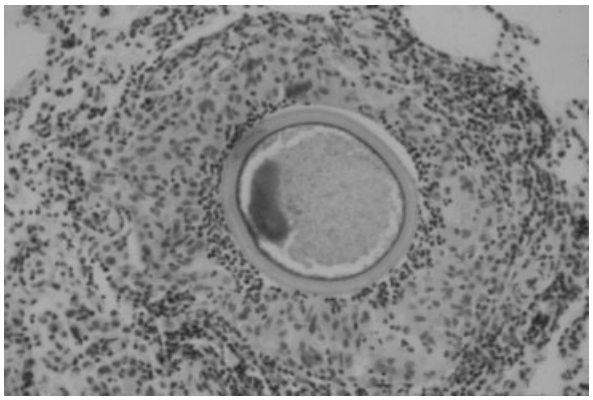

Figure 2 *Histological section of lung of striped skunk showing inflammatory reaction around adiaspore of* E. crescens. *Hematoxylin and eosin; note thick fungal cell wall. (Reproduced, with permission, from Albassam et al. 1986)*

In naturally infected animals, adiaspores occur mostly in lungs within solitary or multiple non-necrotic, sometimes coalescing, granulomas; rarely, adiaspores are extrapulmonary and involve the lymph nodes (Albassam et al. 1986). In severely infected animals, pearl-white or grayish-white nodules measuring up to 1 mm in diameter can be seen on gross examination (Figure 3) (Dowding 1947; Albassam et al. 1986). As with human infections, adiaspores may be found incidentally when only a few are present and the animal is asymptomatic. Large numbers of adiaspores have been found in lungs of trapped rodents with higher numbers in adults compared with juveniles (mean 212.5 versus 177.2) (Hubálek et al. 1995). In the first case of disseminated pulmonary disease in a horse, biopsy examination revealed multiple granulomas composed of an outer layer of epitheloid macrophages and occasional giant cells, and an inner neutrophilic focus surrounding spherical adiaspores of *E. crescens*, 30–80 μm in diameter; at

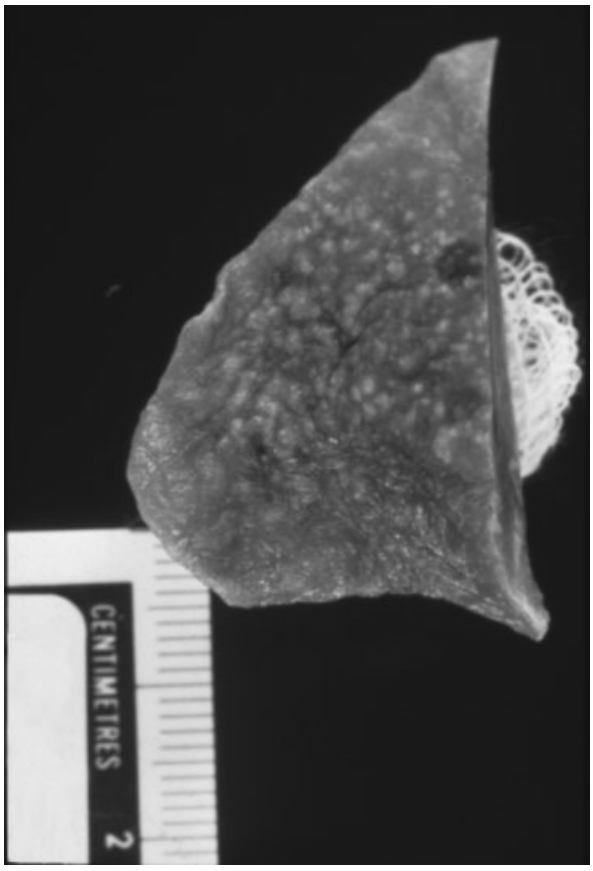

Figure 3 *Formalin-fixed lung of mature striped skunk (*Mephitis mephitis*) showing multiple nodules caused by* Emmonsia crescens. *(Reproduced, with permission, from Albassam et al. 1986)*

postmortem, the lung parenchyma showed diffuse infiltration with 1–2 mm diameter miliary, white nodules (Pusterla et al. 2002). Different inflammatory responses and the absence of reaction around some adiaspores have been explained as arising from repeat exposure, the time involved in maturation of adiaspores or varying antigenicity of the adiaspore wall (Albassam et al. 1986). In animals experimentally infected by intraperitoneal inoculation (Figure 4), between one and several adiaspores develop within granulomas in the liver, spleen, kidney, peritoneum, or other organs (Hejtmanek 1985).

Cytochemistry and structure of adiaspores and hyphae

The adiaspores of *E. crescens* have a complex wall structure, especially when immature (England and Hochholzer 1993) (Figure 5). Cytochemistry has revealed three layers, of which the outer is thinnest and contains the proteins, arginine, tyrosine, and tryptophan, and traces of hydrophilic lipids. The inner wall is thickest and consists of neutral mucosubstances (Hejtmanek 1985). Using transmission electron microscopy, the three layers are almost amorphous or appear as fibrils of different electron densities (Watts et al. 1975; Hejtmanek 1985; Albassam et al. 1986). The innermost layer consists of finer fibrils than the middle layer, while the outer layer appears as irregular heterogeneous fibrils of higher electron density (Watts et al. 1975; Albassam et al. 1986). The middle zone has been described as a fenestrated layer composed of discontinuous dense fibrillar lamellae (Watts et al. 1975). Neutral and acid mucins have been located in the inner and middle layers by colloidal iron and mucicarmine stains (England and Hochholzer 1993). Adiaspores developing on agar demonstrate the hydrolytic enzymes, alkaline and acid phosphatases, nonspecific esterase, aminopeptidase, and respiratory enzymatic activity, including glucose-6-phosphate dehydrogenase, diaphorase, and peroxidase (Kodousek and Hejtmanek 1971; Hejtmanek 1985). Similar enzymatic activity has been reported for hyphae that have cell walls containing chitin, septa with simple pores and Woronin bodies, mitochondria, glycogen granules, vacuoles, lipid bodies, granular endoplasmic reticulum, and numerous nuclei in the hyphal tips (Hejtmanek 1985).

There has been disagreement about the internal structure of adiaspores and about their propensity to divide internally or to replicate by budding. Some authors have indicated that the adiaspores of *E. parva* are uninucleate whereas those of *E. crescens* are multinucleate, and that this factor is associated with unipolar or multipolar budding (Emmons and Jellison 1960; Dvorák et al. 1973; Hejtmanek 1985). Others have found adiaspores to be commonly empty (England and Hochholzer 1993) or to contain lipid vacuoles, mitochondria, and ribosomes with (Hejtmanek et al. 1974) or without (Albassam et al. 1986) nuclei. A form of 'budding' could be induced in the adiaspores of *E. crescens* by changing in vitro growth conditions of immature adiaspores (Emmons 1964), but most investigators now agree that, in the host, adiaspores demonstrate neither budding nor internal replication.

IMMUNODIAGNOSIS

There is no reliable serological test for the diagnosis of adiaspiromycosis. Environmental exposure to *Emmonsia* spp. was first detected by positive skin-test reactions to antigens prepared from culture extracts in a group of school children, some of whom also demonstrated reactivity to coccidioidin (Emmons and Ashburn 1942). Delayed-type hypersensitivity reactions to antigens of *E. crescens* and precipitating antibodies in sera can be demonstrated in humans with infections (Tomšíková et al. 1970, 1974; Simecek et al. 1982). Antigenic activity has been found to vary among strains and to be greater in the parasitic stage (Tomšíková et al. 1972, 1976, 1978). Both strain- and species-specific antigens were

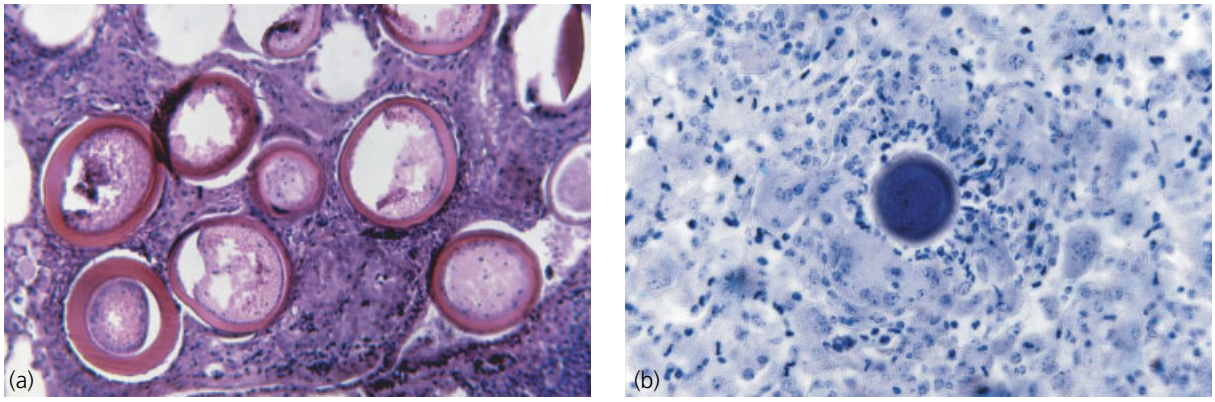

Figure 4 *Histological sections of mouse lung after experimental inoculation showing* **(a)** *numerous thick-walled adiaspores of* E. crescens *and* **(b)** *solitary thin-walled adiaspore of* E. parva.

detected by immunodiffusion tests, using antisera raised against partially purified cytoplasmic antigen (Cano and Taylor 1974). A passive cutaneous anaphylaxis test in young guinea pigs detected two possible cases of human infection among donors of 83 sera collected from trappers and mammologists who handled a variety of animals in their work (Jellison et al. 1962). Immunization with specific antiserum achieved some inhibition of adiaspore development in experimentally infected animals (Tomšíková et al. 1982).

Immunological crossreactivity has been demonstrated between *Emmonsia* spp. and *B. dermatitidis* and *H. capsulatum* (Tomšíková et al. 1970; Al-Doory et al. 1971; Sekhon et al. 1986), but not with *C. immitis* (Pusterla et al. 2002). Nonspecific precipitin lines are produced in exoantigen tests between *E. parva* antisera and the A antigen of *B. dermatitidis* or the H and M antigens of *H. capsulatum*, but the exoantigen is considered reliable in differentiating among the species (Sekhon et al. 1986; Kwon-Chung and Bennett 1992; Padhye et al. 1994). A commercially available DNA probe for *B. dermatitidis* was found to show crossreactivity with *P. brasiliensis* but not with *E. parva* (Padhye et al. 1994). In exoantigen tests, no crossreactivity was found between *E. pasteuriana* and *B. dermatitidis*, *H. capsulatum*, or *C. immitis* (Gori et al. 1998).

LABORATORY DIAGNOSIS

Direct examination and isolation

Diagnosis of adiaspiromycosis is generally made by observation of characteristic adiaspores by histopathology. Based on the larger size of the adiaspores, most reports concern *E. crescens*. The fungus is rarely cultured from specimens in cases of human infection. The differential clinical diagnosis is complicated by mimicking of other syndromes (including other fungal infections, tuberculosis, sarcoidosis, idiopathic granulomatous disease, etc.) and this may lead to failure to perform fungal culture. However, even if adiaspiromycosis is suspected, fungal culture of sputum, bronchial washings, or bronchoalveolar lavage is often negative (Barbas Filho et al. 1990; England and Hochholzer 1993).

Most *Emmonsia* isolates have been recovered from dissected animal lung tissue. In the case of a horse with disseminated pulmonary adiaspiromycosis, culture was negative from lung tissue and from transtracheal

aspirate, but etiology of the fungus as *E. crescens* was confirmed by the adiaspores measuring 30–80 μm and by polymerase chain reaction (PCR) assay of the tissue (Pusterla et al. 2002). The sequence of the PCR-amplified DNA fragment from the lung was found to be identical to an LSU-rDNA sequence on deposit in GenBank for an *E. crescens* isolate (accession number AF038335, Peterson and Sigler 1998). *Emmonsia*-like isolates are occasionally cultured from human respiratory or cutaneous specimens, but the significance of these isolates is difficult to evaluate when information on results of direct examination is lacking (Peterson and Sigler 1998). The fungus is occasionally isolated from other substrates including soil, dung, or straw.

By contrast, culture is usually successful from specimens of patients with AIDS. In the osteomyelitic infection attributed to *E. parva*, direct examination of pus showed oval to elongated thick-walled cells lacking internal contents; the fungus was isolated from pus, sputum, and bone marrow (Echavarria et al. 1993). The fungus was grown from a respiratory specimen of a male patient with pulmonary infection and advanced AIDS (Turner et al. 1999). *E. pasteuriana* was isolated with some difficulty from a cutaneous lesion in the Italian patient with AIDS (Gori et al. 1998). Although disseminated cutaneous lesions were present, these were all culture negative except for the last biopsy taken just before death.

Mycology

The colonial and microscopic features of *Emmonsia* spp. resemble those of their closest relative, *B. dermatitidis*. *Emmonsia* spp. differ in their propensity to form one to three conidia at the ends of narrow, often slightly swollen stalks, in the conidia being flattened and as broad as they are long, and in their growth responses at higher temperature (Table 1). Conidia are aleurioconidia, i.e. solitary conidia released by lytic disintegration of part of the supporting hyphal cell (Carmichael 1962; Sigler, 1996, 1997, 2003). The colonial features of *Emmonsia* spp. are shown in Figures 6 and 38.7 and compared with a typical colony of *B. dermatitidis* shown in Figure 8. Microscopically, *Emmonsia* spp. appear similar to each other (Figure 9) (Table 1). Conidia are single celled and formed on the sides of the hyphae (sessile) or at the ends of a short narrow stalks which are either nonswollen or slightly swollen at the end closest to the conidium. Commonly, two or three conidia are arranged at the tips of spine-like pegs arising by secondary proliferation from the swollen cell. Conidia appear slightly flattened and slightly broader than long (subglobose or oval) or are pyriform and have narrow basal scars. Conidia of *E. crescens* and *E. parva* have smooth walls

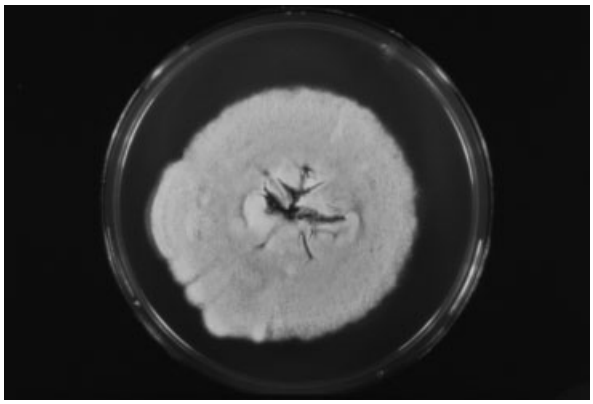

Figure 6 *Velvety, buff colored colony of* E. crescens *on phytone yeast extract agar after 28 days at 25°C (UAMH 7365). Note that colonies demonstrate variation in color and texture.*

and measure 2.5–4 μm long and 3–5 μm wide, but they may swell in age and become finely roughened. Up to eight conidia are formed in *E. pasteuriana* and they measure 2–5.5 μm long by 2–3.5 μm wide; conidia are smooth to finely roughened or appear tuberculate by scanning electron microscopy.

Emmonsia spp. grow well on routine mycological media including Sabouraud's glucose agar without cycloheximide, but conidiation is enhanced on media such as potato dextrose agar (PDA). *Emmonsia* spp. are slightly to moderately inhibited on media containing cycloheximide at a concentration of 400 μg/ml; *E. crescens* is less tolerant than *E. parva* (Sigler 1996). Isolates of both species vary in growth rates, morphology, and color (Otcenášek and Zlatanov 1975; Sigler 1996). On PDA, colonies reach diameters of 4.5–8 cm after 4 weeks at 25°C and may be glabrous (smooth or bald), woolly, velvety, or coarsely powdery. Colonies are flat, raised in the center, or radiately folded and the color varies from white to yellowish-white, buff, or tan (Sigler 1996). Two main colony

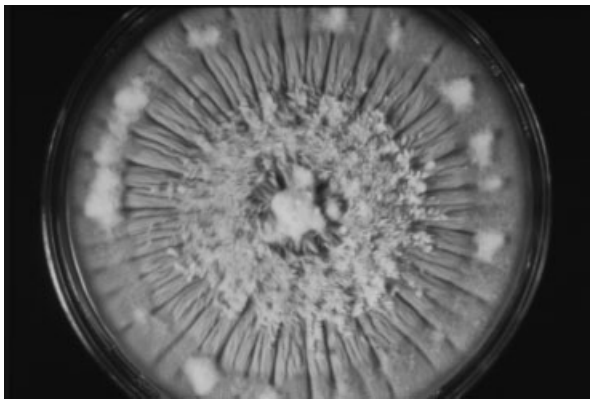

Figure 7 *Glabrous to hairy yellowish-white colony of* Emmonsia parva *on phytone yeast extract agar after 28 days at 25°C (UAMH 134). Note that colonies demonstrate variation in color and texture.*

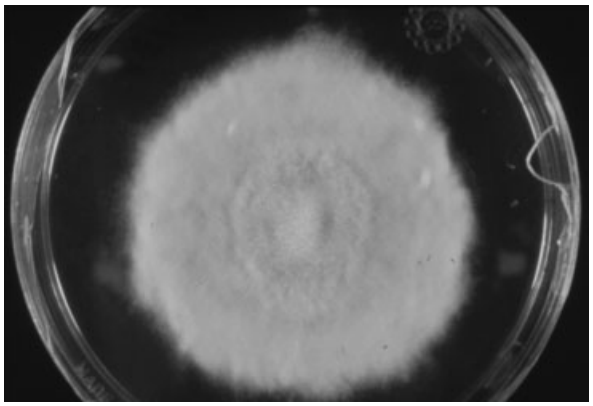

Figure 8 *Buff colored colony of* B. dermatitidis *on phytone yeast extract agar after 28 days at 25°C (UAMH 5438). (Compare with Figure 6)*

types may be observed, but intermediate forms are common (colony colors are described according to the color charts of Kornerup and Wanscher 1978). One type is yellowish-white to orange-white (4A2/5B3), with a densely woolly center dotted with exudate droplets, and having a broad glabrous margin. The reverse of the colony is grayish-brown (6D3). A second type is pale orange to grayish-orange (5A3/B5), with a coarsely powdery center and an irregular margin. Exudate droplets are present or absent and the reverse is reddish-brown (8E4). Colonies of *E. pasteuriana* are similar in being yellowish-white (4A2), densely woolly, furrowed, or zonate with powdery or glabrous sectors.

Emmonsia spp. are distinguished by their growth responses at higher temperature. In vitro, isolates of *E. crescens* are almost completely inhibited at 37°C and some strains show restricted growth even at 30°C (Boisseau-Lebreuil 1981; Sigler 1996). At 35–37°C, conidia in the residual inoculum develop into globose swollen cells or adiaspores which measure 20–140 μm in diameter (average 59 μm) (Figure 10). These cells are thinner walled than those formed in vivo and have sometimes been given other names (e.g. chlamydospores or trophocytes) (Carmichael 1962; Dvorák et al. 1973). Maturing adiaspores germinate from many sites if transferred to culture media at lower temperatures (25°C) (Emmons 1964; Boisseau-Lebreuil 1970; Hejtmanek 1976). At 37°C, isolates of *E. parva* form colonies ranging from 9 to 77 mm in diameter after 21 days but are almost completely inhibited at 40°C (Sigler 1996). Adiaspores formed at this temperature are smaller than those of *E. crescens* and range from 8 to 20 μm in diameter (mean 12 μm). Complete conversion of hyphae to adiaspores is rarely achieved. When grown on enriched media such as brain heart infusion agar at 37°C, *E. pasteuriana* converts to a yeast phase consisting of oval to lemon-shaped, small (2–4 μm) yeast-like cells having narrow-based buds (Table 1) but conversion is incomplete and hyphal forms are present.

Teleomorphs and relationships

Recently, classical mating experiments and DNA sequence comparisons have provided evidence that *Emmonsia* spp. are anamorphs (mitotic, asexual stages) of *Ajellomyces* spp. and that their closest relative is *B. dermatitidis*. Species of *Ajellomyces* are heterothallic and teleomorphs (meiotic, sexual stages) form when compatible isolates are mated. Ascocarps are composed of branched, anastomosing, pale-brown hyphae, in which individual cells are somewhat diamond shaped, and terminate in coiled appendages. Ascospores are small (<1–1.5 μm diameter) and covered with minute spiny projections. The teleomorph of *B. dermatitidis* is *Ajellomyces dermatitidis* (McDonough and Lewis 1967, 1968); that of *H. capsulatum* was described first as *Emmonsiella capsulata* but later renamed as *Ajellomyces capsu-*

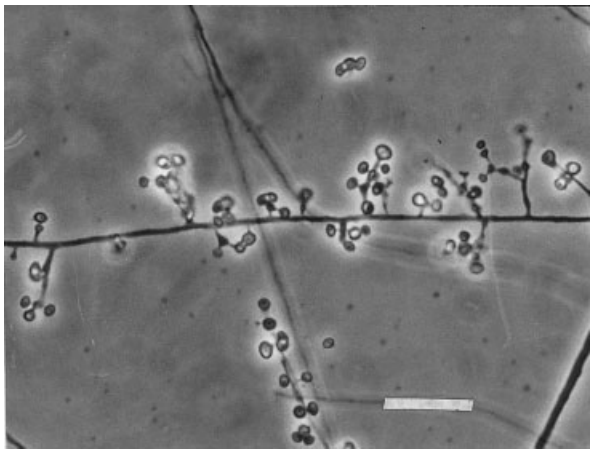

Figure 9 *Microscopic morphology of* E. crescens *(UAMH 7365). In* Emmonsia species*, one to three conidia are borne at the ends of stalks which are commonly slightly swollen. Bar, 20 μm. (Reproduced, with permission, from Sigler 1996)*

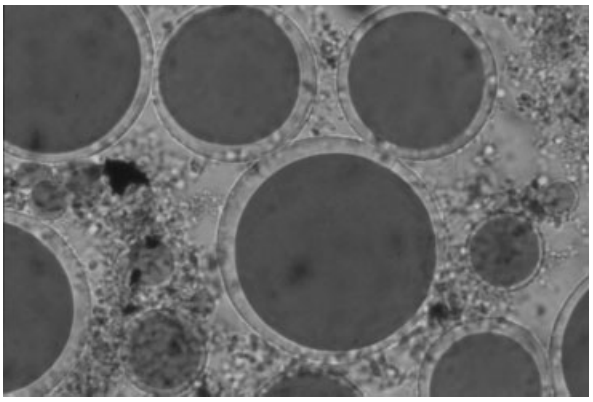

Figure 10 *Adiaspores of* Emmonsia crescens *formed in vitro on phytone yeast extract agar at 37°C (UAMH 7365) and stained with acid fuchsin in lactic acid.*

latus (Kwon-Chung 1972; McGinnis and Katz 1979). Matings among 12 strains of *E. crescens* resulted in a teleomorph described as *Ajellomyces crescens* (Sigler 1996) (Figures 11–14). However, no fertility was seen among mated isolates of *E. parva* or when isolates were paired with those of *E. crescens*.

Phylogenetic trees derived from comparison of DNA sequences obtained from the ribosomal rRNA gene confirm the relationship among these species. *Emmonsia* spp. and *B. dermatitidis*, together with *H. capsulatum*, *Paracoccidioides brasiliensis*, and *Lacazia loboi* (not known in culture), are placed as members of the monophyletic *Ajellomyces* clade (Bowman and Taylor 1993; Leclerc et al. 1994; Drouhet et al. 1998; Peterson and Sigler 1998; Herr et al. 2001; Untereiner et al. 2002; Sigler 2003). Although *Ajellomyces* was classified in the family *Onygenaceae,* order Onygenales (Currah 1985), phylogenetic analyses of DNA sequence data have shown the *Ajellomyces* clade to be a lineage distinct from the *Onygenaceae* (Sugiyama and Mikawa 2001; Untereiner et al., 2002). The new family *Ajellomycetaceae* has been proposed for this lineage (Untereiner et al. 2004). Although the *Ajellomyces* clade is well supported, the relationships within it are not clearly resolved. *P. brasiliensis* is in the clade, but its position is not well defined. *C. immitis* is placed within the *Onygenaceae* and apart from *Ajellomyces* species; its closest relative is a nonpathogenic species *Uncinocarpus reesii* (*Malbranchea* anamorph) (Sigler and Carmichael 1976; Bowman and Taylor 1993; Pan et al. 1994; Sugiyama and Mikawa 2001).

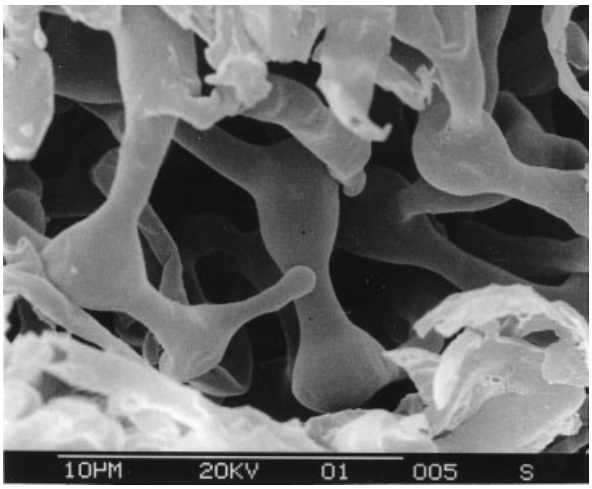

Figure 12 *Scanning electron micrograph showing the swollen, diamond-shaped cells of the hyphae composing the ascocarp (UAMH 128 × 129). (Reproduced, with permission, from Sigler 1996)*

Phylogenetic analysis of *Emmonsia* isolates based on LSU-ITS rDNA sequences placed *E. crescens* isolates into two groups according to their geographical origin and found greater than expected variation among isolates identified as *E. parva*, leading to the suggestion that additional species exist, and that some human associated isolates may represent undescribed species (Peterson and Sigler 1998). *E. parva* isolates originally obtained by Emmons from rodents in Arizona were found to be genetically closer to *B. dermatitidis* than to *E. crescens*. Guého et al. (1997), comparing LSU rDNA sequences, found almost the same level of

genetic diversity between African and North American isolates of *B. dermatitidis* as between the latter and *E. parva*. A later study showed that *E. pasteuriana*, which demonstrates a yeast form in vivo, is closer to *E. crescens* than to *B. dermatitidis* (Drouhet et al. 1998). The close relationship between *Blastomyces* and *Emmonsia*, and the finding that some human-associated *Emmonsia* spp. produce budding cells in vivo, suggests that these anamorph taxa should be combined. Similar arguments have been made previously and species of both genera were at one time placed in *Chrysosporium*. An impediment to combining the species in *Blastomyces* comes from the fact that the *Blastomyces* Gilchrist & Stokes is illegitimate according to the Botanical Code. To have this medically important genus retain priority over *Emmonsia*, it must first be conserved (Peterson and Sigler 1998).

Differential diagnosis

Diagnosis of adiaspiromycosis is generally based on radiological presentations and the finding of characteristic adiaspores in tissue. In culture, isolates of *Emmonsia* spp. resemble those of *B. dermatitidis*, but cultures are rarely established from patients with pulmonary adiaspiromycosis. *E. crescens* and *E. parva* do not convert to a yeast form, and their strongly inhibited growth and formation of adiaspores in culture at 37°C or 40°C, respectively, may aid in identification (Sigler 1996). *B. dermatitidis* isolates, by comparison, convert to the yeast form typical for the species (large thick-walled cells with broad-based buds) and are more tolerant of cycloheximide (Table 1). *B. dermatitidis* isolates can be confirmed by the DNA probe or exoantigen test (Table 1). Microscopically, conidia of *B. dermatitidis* are usually solitary at the ends of stalks with rare proliferation to form another conidium, in contrast to those of *Emmonsia* spp. which often demonstrate secondary proliferation (Figure 9).

TREATMENT

The optimum therapeutic protocol for patients with pulmonary adiaspiromycosis is not clear, but association of a steroid with an antifungal drug appears to aid recovery (de Almeida Barbosa et al. 1997). These authors reviewed the outcome of therapy for three Brazilian patients and case histories for 16 other patients. Two of three Brazilian patients improved without therapy. A third did not respond to itraconazole alone but recovered when prednisone was added to the regimen. A few patients have shown improvement after therapy with steroids alone (Kodousek et al. 1971; Vojtek et al. 1971), amphotericin B alone (de Almeida Barbosa et al. 1997) or in combination with flucytosine (Quilici et al. 1977) or prednisone (de Almeida Barbosa et al. 1997), ketoconazole (Severo et al. 1989; Moraes et al. 2001), and antituberculosis agents (Simecek et al. 1982). Improvement in one case followed therapy with thiobendazole, although in vitro susceptibility tests demonstrated that *E. crescens* was resistant at concentrations up to 128 μg/ml, whereas *E. parva* was sensitive at 1 μg/ml (Barbas Filho et al. 1990). Mycelial stages of both *E. crescens* and *E. parva* are sensitive to imidazoles by in vitro susceptibility tests (Otcenášek and Ditrich 1983). Although *E. crescens* appears less sensitive to amphotericin B in vitro (minimal inhibitory concentration 4 μg/ml) (Otcenášek and Hubálek 1968), enlargement of conidia into adiaspores in experimentally infected mice was prevented by treatment with amphotericin B (Otcenášek and Dvorák 1967).

Infection in two AIDS patients responded to therapy with amphotericin (Echavarria et al. 1993) or amphotericin followed by fluconazole (Turner et al. 1999). However, a third patient whose CD4 counts were very low, died after a short course of therapy with amphotericin (Gori et al. 1998).

History of human parasitology

F.E.G. COX

Human evolution and parasitic infections 1
Helminths and helminth infections 3
Protozoa and protozoal infections 11
Summary and conclusions 16
References 17

The history of parasitology embraces three interconnected fields: zoology, with its interests in parasites for their own sakes, veterinary medicine, and human medicine, particularly tropical medicine. During our relatively short history on Earth we humans have acquired about 300 species of helminth worms and over 70 species of protozoa (Ashford and Crewe 2003) of which a small proportion cause some of the most important diseases in the world, particularly in the tropics. In this chapter it is only possible to deal with those parasites that are the most common and which cause the most important diseases.

HUMAN EVOLUTION AND PARASITIC INFECTIONS

Human evolution and the acquisition of parasitic infections cannot be separated and, in order to understand the history of parasitology, we have to delve deeply into the past. It is now widely accepted that our species, *Homo sapiens*, emerged somewhere in Africa, but we do not know exactly where or when; opinions on this subject are extreme. Molecular evidence dates our origins to somewhere between 150 000 years ago in eastern Africa (Tishkoff et al. 2001) and 60 000 years ago in the northern part of southern Africa (Wells 2002). The details are not really relevant to us here, but what is important is that most authorities agree that our early ancestors spread from Africa throughout the world in several waves (Templeton 2002) until, at the end of the last Ice Age, about 11 000 years ago, humans had migrated to, and inhabited, virtually the whole of the Earth. During these migrations humans were not alone and brought with them various parasites as 'heirlooms,' inherited from primate ancestors in Africa, and 'souvenirs,' acquired from animals encountered during these migrations. Agriculture, the practice of domesticating animals, and the development of settlements and cities increased the opportunities for the transmission of infections between animals and humans and between humans. Later, the opening up of trade routes brought parasitic infections to new geographical regions, for example, colonization and the slave trade brought new parasites to the New World from the Old World (Desowitz 1997).

For many years the distribution of parasites in the past has been largely a matter of speculation, but we have now begun to learn a lot about the past history of parasitic infections from studies of archeological artifacts such as the presence of helminth eggs or protozoan cysts in coprolites (fossilized or desiccated feces) and naturally or artificially preserved bodies. From such studies a new science, palaeoparasitology, has emerged and some examples of these discoveries will be discussed later.

Written records

Direct evidence concerning our knowledge of parasites in the past is fragmentary, so we have had to rely heavily on the written record. The first written records date from a period of Egyptian medicine between 3000 and 400 BC, particularly the papyri of 1500 BC discovered by Georg Ebers at Thebes (Bryan 1930). Many diseases, specifically fevers, are described in detail in the writings of Greek physicians between 800 and 300 BC, the best known being the collected works known as the *Corpus*

Hippocratorum (see Jones and Whithington 1948–1953). Physicians from other civilizations also made significant contributions to our understanding of parasitic diseases and there are extensive writings from China (3000–300 BC), India (2500 – 200 BC), Rome 700 BC – 400 AD, and the Arab Empire (latter part of the first millennium). Two important Arabic medical works that include a great deal of information about diseases caused by parasites are *Al-hawi* by Rhazes (850–923) and *Al canon fi al tib* by Avicenna (980–1037).

Religious and superstitious beliefs in the Dark and Middle Ages held back medical progress in Europe, and it was not until the Renaissance that scientific and medical revolution freed scientists from the chains of superstition and religion and unleashed a period of spectacular investigation that gradually led to the great discoveries of the 19th century. These include the renunciation of the theory of spontaneous generation and the development of the 'germ theory', by Louis Pasteur; the demonstration that diseases are caused by bacteria, also by Pasteur; the discovery of viruses, by Pierre Emile Roux; the introduction of methods of preventing diseases caused by microorganisms, by Robert Koch; and the incrimination of vectors in the transmission of parasites, by Patrick Manson.

Tropical diseases

Most commentators date the origin of tropical diseases as a distinct branch of medicine to 1898 when Sir Patrick Manson, now universally regarded as the 'father of tropical medicine,' published the first edition of his *Tropical Diseases* (Manson 1898). The important tropical diseases described by Manson included a number caused by parasites – malaria, sleeping sickness, amoebic dysentery, kala azar, and bilharzia – but Manson did not consider parasitology to be a distinct branch of tropical medicine.

Michael Warboys has suggested that 'the dominant tradition of the history of tropical diseases has been to celebrate the discoveries of the etiologies of the classic group of vector-borne parasitic diseases in the period 1870–1920' (Warboys 1993). There is, however, much more to the history of tropical diseases than this and it is now clear that the work of those who investigated parasitic diseases in the centuries before Manson should not be dismissed as irrelevant to our understanding of these diseases. Nor should the discoveries of the 20th-century workers be regarded as mere finishing touches to previous knowledge. Scientific progress during any period of history depends on the availability of techniques and of individuals capable of using and interpreting the information that becomes available. The remarkable thing about the last decades of the 19th century was the coming together of so many new ideas and personalities.

Parasitic diseases have always held a fascination for travelers, clinicians, and scientists. Some, such as sleeping sickness, are unique to the tropics; others, such as malaria, are of particular importance in the tropics but also extend into more temperate regions; still others, such as hookworm, have worldwide distribution (either now or in the past). The present distribution of parasitic diseases tends to reflect the success of hygiene and control measures in the more developed parts of the world rather than any clear geographical or climatic restriction. Thus, many parasites that were once widespread are now found in only the warmer and poorer parts of the world and are considered as 'exotic' diseases when imported into the cooler northern and southern latitudes where they were once prevalent. The term 'tropical diseases' has now become one of convenience rather than a definitive description

The history of parasitology has been well served in the scientific literature, particularly in works devoted to tropical medicine. As well as the publications already mentioned there is a considerable amount of information about the history of parasitology in the more general works by Scott (1939), Ackernecht (1965), Brothwell and Sandison (1967), Campbell et al. (1992), Chernin (1977), Cox (1996), Mack (1991), Norman (1991), Ranger and Slack (1992), and Ransford (1983). More specifically, there are a number of publications dedicated to the history of parasitology, including those of Cook (2001), Cox (2002, 2004a), Foster (1965), Garnham (1970), Hoeppli (1956, 1959), Kean et al. (1978), Moore (1976), and Warboys (1983). The most comprehensive work on the history of any aspect of parasitology, one that will be impossible to emulate, is David Grove's *A history of human helminthology* (Grove 1990), which contains over 800 pages of detailed accounts of all the discoveries in human helminthology and allied fields. *The Wellcome Trust illustrated history of tropical diseases* (Cox 1996) contains chapters on most of the important human parasitic infections. Foster's *A history of parasitology* (Foster 1965) covers some, but not all, important parasitic infections. In addition, there are a number of important monographs mainly relating to the associations between parasitic infections and human endeavor and welfare, and these will be mentioned in the appropriate places.

Helminth worms, being large and easily recognizable, and common parasites of domesticated and wild animals, very soon attracted the attention of zoologists who, schooled in the concepts of comparative zoology, treated parasites in the same way as any other group of animals and tended to ignore the fact that they also caused disease. Veterinarians and clinicians, on the other hand, were quick to note the implications of these infections and to draw parallels between parasitic infections in domesticated animals and humans and discoveries in the field of zoology. To this day, helminthology is usually regarded as a branch of zoology. Protozoa, being

microscopic, had to await the development of the microscope before they were first recognized; the history of the protozoa, therefore, parallels that of other microorganisms and has largely been the province of medicine rather than zoology. There is thus a dichotomy that is not always apparent in that the interest of most helminthologists has centered on the worms themselves and, to a lesser extent, the diseases they cause whereas, in contrast, scientists interested in parasitic protozoa have tended to focus predominantly on diseases. There are other obvious reasons for this dichotomy; for example, the fact that helminths are multicellular organisms and can be examined outside their hosts has facilitated physiological and biochemical studies, whereas isolating protozoa from their host cells has proved to be very difficult. These differences in approach have had a marked effect on our understanding and interpretation of the history of parasitology. Although discoveries about the helminths and protozoa originally tended to run on parallel paths, these paths converged at the end of the 19th century when Patrick Manson introduced the medical and veterinary world to the concept of vector-borne parasitic diseases and brought entomologists into the field of parasitology. Thereafter, research and teaching institutions have traditionally considered protozoology, helminthology, and entomology as three interrelated fields.

The history of parasitology embraces some of the most exciting discoveries ever made in medicine, and these findings have had an impact well outside their immediate field. For example, the discovery of the vector-borne nature of the filarial worms influenced ideas about the transmission of malaria which, in turn, led to the discovery of the mosquito-borne transmission of yellow fever, the whole field of arboviruses, and the implication of other vectors in trypanosomiasis, relapsing fever, and plague. Similarly, the discovery that trypanosomes caused diseases in both animals and humans opened up a new field of zoonoses (infections common to animals and humans) and the study of reservoir hosts for a number of infections.

Many of the great discoveries in parasitology were made over a relatively short period, in the 30 years between 1885 and 1915, when major advances were also being made in our understanding of other infectious diseases. The great personalities of this period made discoveries in a number of fields, and their findings and ideas fed off one another. The names of Pasteur, Koch, Bruce, and Manson occur time and time again in the history of parasitology and microbiology.

The history of parasitic diseases can be considered as a number of phases: the recognition of the disease; the discovery of the organism involved; the connection between the organism and the disease; the consolidation of all these strands; and the application of this knowledge to control schemes.

So vast is the field of human parasitology, with its many and far-reaching discoveries, that it is not possible to do justice to the whole subject and in the rest of this chapter only the most significant aspects will be discussed. No attempt will be made to discuss the parasites or the diseases they cause other than briefly, and the reader is referred to other chapters in this volume to provide the necessary background information and details.

HELMINTHS AND HELMINTH INFECTIONS

Discovery of the organisms

Given the ubiquitous nature and large size of the helminth worms, it would be surprising if our earliest ancestors had not been aware of the more common types; evidence for this assumption comes from the fact that in primitive tribes in Sarawak and North Borneo most people are aware of their intestinal roundworms and tapeworms (Hoeppli 1959). Much has been made of quotations from the Bible on the subject of helminth worms, but these are often open to several interpretations; the only conclusion that can be safely drawn is that those who contributed to the Bible were aware of the existence of parasitic worms (i.e. we cannot conclude that they possessed any detailed knowledge of the subject). With the first written records by physicians we are on firmer ground. The Egyptian medical papyrus usually referred to as the *Papyrus Ebers*, dating from around 1500 BC, refers to intestinal worms and these records are backed by the discovery of calcified helminth eggs in mummies dating from 1200 BC. The Greeks, Aristotle (384 – 322 BC) in particular, were familiar with a range of parasites from humans and also domesticated and wild animals. Greek and Roman physicians, including Hippocrates (460 – 375 BC), Celsus (25 BC – AD 50), and Galen (129 – 200 AD), were familiar with the human roundworms, *Ascaris lumbricoides* and *Enterobius vermicularis*, and tapeworms. In fact, the terms 'roundworm' (helmins strongyle) and 'ribbon worm' (helmins taenia) can be traced back to the earliest Greek records (Grove 1990). Paulus Aegineta (625–690) clearly described *Ascaris*, *Enterobius*, and tapeworms, and gave good clinical descriptions of the infections they caused. With the decline and fall of the Roman Empire, the study of medicine switched to Arabic physicians. Avicenna recognized not only *Ascaris*, *Enterobius*, and tapeworms but also the Guinea worm, *Dracunculus medinensis*, a worm that had been recorded in parts of the Arab world, particularly around the Red Sea, for over 1 000 years.

The medical literature of the Middle Ages is very limited, but the existence of parasitic worms was widely

recorded and, in many cases, these were regarded as the possible causes of a number of diseases. Unfortunately, many of these 'worms' were fictitious, as were the symptoms ascribed to their presence, for example toothache and heart attacks (Hoeppli 1959). On the other hand, Chinese physicians believed that humans should harbor at least three worms to be in good health, and this belief that worms were beneficial also extended into Europe (Foster 1965).

The history of helminthology really took off in the 17th and 18th centuries following the re-emergence of science and scholarship during the Renaissance. In his *Systema Naturae*, Linnaeus described six helminth worms: *Ascaris lumbricoides*, *Ascaris vermicularis* (= *Enterobius vermicularis*), *Gordius medinensis* (= *Dracunculus medinensis*), *Fasciola hepatica*, *Taenia solium*, and *Taenia lata* (= *Diphyllobothrium latum*) (Linnaeus 1758). Thereafter there was a gradual accretion of new species; nine species were identified by 1782, with the addition of *Trichuris trichiura*, *Taenia saginata*, and *Echinococcus granulosus*. This number remained virtually unchanged in various texts published between 1800 and 1819 but was subsequently extended by the inclusion of *Trichinella spiralis* and *Loa loa* by 1845; *Ancylostoma duodenale*, *Schistosoma mansoni*, and *Hymenolepis nana* by 1855; and *Strongyloides stercoralis*, *Wuchereria bancrofti*, *Clonorchis sinensis*, *Fasciolopsis buski*, *Paragonimus westermani*, *Heterophyes heterophyes*, *Schistosoma haematobium*, and *Dipylidium caninum* between 1885 and 1890 (see Grove 1990).

By the beginning of the 20th century, 28 species had been recorded in humans, a number that has grown to >300 species including accidental and very rare records (Coombs and Crompton 1991; Ashford and Crewe 2003). Of these, about 80 can be regarded as fairly common and about 20 very common. The description of a new species of helminth worm in humans is now very unusual, but advances in biochemistry and molecular biology permit the identification of minute but significant differences between parasites and this is likely to lead to the creation of additional species and subspecies from within the current list.

Our understanding of parasitology could not really progress until the theory of spontaneous generation had been disproved. Doubts had been raised about the validity of this concept in the 17th century, but it still persisted until the definitive experiments of Pasteur at the end of the 19th century. A number of helminthologists were among those who had begun to doubt the concept, including Francesco Redi and Edward Tyson who, in the 17th century, went so far as to describe sexual reproduction in worms. Studies on the biology and life cycles of helminth worms effectively destroyed the theory of spontaneous generation (see Farley 1977) well before Pasteur delivered its deathblow and promulgated the 'germ theory' of infection.

Table 1 lists some of the most important events in our knowledge and understanding of parasitic worms. Note the massive activity that occurred at the end of the 19th and beginning of the 20th centuries.

ASCARIS AND ASCARIASIS

Ascaris lumbricoides, the large roundworm, is one of the six worms listed by Linnaeus and its name has remained unchanged ever since. Human infections are worldwide, with >250 million people infected. The presence of this worm, which is often voided in the feces, is very obvious and its existence has been recorded from Egyptian medical papyri of 1500 BC, the works of Hippocrates in the 5th century BC (see Jones and Whithington 1948–1953), Chinese writings of the 2nd and 3rd centuries BC, and the texts of Roman and Arabic physicians from the 1st to 10th centuries AD (see Grove 1990; Goodwin 1996b). Direct evidence of the antiquity of human infections comes from the discovery of eggs of *Ascaris* in human coprolites dated 227 BC from Peru (Horne 1985), in Egyptian mummies from 1938 –1600 BC (Cockburn et al. 1998) and in Chinese mummies from 1368 – 1644 BC (Dexian et al. 1981). This worm is so common that it is impossible to say who discovered it, but the first scientific accounts of its anatomy were by Edward Tyson (1683) and Francesco Redi (1684). The mode of infection by the ingestion of eggs was established by Casimir Davaine (1862) and Giovanni Grassi (1881) who infected himself and later found eggs in his feces. The whole life cycle, including the migration of the larval stages around the body, was worked out in 1922 by Shimesu Koino who also infected himself and deduced the life cycle when he found eggs in his sputum (Koino 1922).

TRICHINELLA AND TRICHINOSIS

Trichinosis, also known as trichinellosis and trichina infection, is caused by the nematode worm *Trichinella spiralis* and is usually acquired by eating infected pork. Foster (1965) considers this to be one of the most interesting parasitic infections and more likely to be responsible for some religious traditions of avoiding pork than the possibility of tapeworm infection (see below). Although the association with pigs had been recognized since the earliest times, the encysted larvae in the muscle were not seen until 1821 and even then their presence was not associated with disease. The story of the association between the worm and human infection is described in full by Foster (1965) and Grove (1990) and can only be summarized here. It revolves around the discovery of the encysted larvae of the worm in humans in 1835 by James Paget, a medical student at St Bartholomew's Hospital in London; this discovery led to intensive investigations by some of the world's most important parasitologists including Rudolf Leuckart, Rudolph Virchow, Thomas

Table 1 *Important events in the history of our knowledge and understanding of parasitic worms.*

Date	Event
c. 5000 BC	Hookworm ova in a human (?) coprolite from Brazil
c. 2500 BC	*Paragonimus* ova in human coprolites from Chile
c. 2330 BC	*Ascaris* ova coprolites from Peru
c. 2000 BC	*Taenia* ova in an Egyptian mummy
c. 1500 BC	*Papyrus Ebers* (Egypt): reference to roundworms (*Ascaris lumbricoides*), threadworms (*Enterobius vermicularis*), and tapeworms (*Taenia* spp.)
1250–1000 BC	*Schistosoma haematobium* eggs in Egyptian mummies
1300–1234 BC	Biblical references to *Dracunculus medinensis* in Red Sea region
c. 800 BC	*Ancylostoma* worms in a Peruvian mummy
c. 600–700 BC	Records of *Dracunculus medinensis* worms from Mesopotamia
c. 400 BC	*Corpus Hippocraticorum* (Aphorisms and Epidemics): references to roundworms (*Ascaris lumbricoides*), threadworms (*Enterobius vermicularis*, *Echinococcus granulosus*, and hydatid disease
500–400 BC	Hookworm eggs in coprolites from Brazil
c. 384–322 BC	Aristotle refers to cysticerci in tongues of pigs and distinguishes between large and flat worms (*Taenia*), cylindrical worms (*Ascaris*), and thin worms (*Enterobius*)
c. 300 BC	Chinese descriptions of threadworms, tapeworms, hookworms, and hookworm disease
200–300 BC	*Chinese Book of Plain Questions* mentions *Ascaris*
167 BC	*Clonorchis* ova from China
AD 20	Celsus recognizes tapeworms taenia, tinea, and taeniola (*Taenia* spp.), vermes cucurbitini (tapeworm proglottids), 'hailstones' (cysticerci) and roundworms, lumbrici teretes (*Ascaris lumbricoides*)
AD 27–39	Pliny describes tapeworms in Egyptians (presumably *T. saginata* because pork was not eaten) and *Tinea rotunda* (Ascaris)
130–200	Galen recognizes three types of worms: roundworms (*Ascaris lumbricoides*), threadworms (*Enterobius vermicularis*), and tapeworms (*Taenia* spp.) and also cysticerci in livers of slaughtered animals
c. 900	Hookworms in a pre-Columbian Andean mummy
c. 1000	Avicenna (Ibn Sina) refer to 'four kinds of worms'
c. 1340	Johannes Actuarius (a Byzantine physician) describes *Trichocephalus trichiuris* (=*T. trichiura*).
1379	Jehan de Brie refers to *Fasciola hepatica* from sheep
1592	Dunus discovers *Diphyllobothrium latum*
1602	Plater distinguishes betweem *Diphyllobothrium* and *Taenia*
1634	Herbert describes *Dracunculus medinensis* worms in the leg
1674	Welsch makes a detailed study of *Dracunculus medinensis* and dracunculiasis
1683	Tyson describes the anatomy of *Ascaris lumbricoides*
1683	Tyson discovers the scolex of *Taenia solium*
1684	Redi describes helminths from domestic and wild animals and arranges them according to their hosts
1684	Redi recognizes parasitic nature of *Echinococcus* cysts
1700	Andry publishes *De la génération des vers dans le corps de l'homme*, the first textbook on medical parasitology, in which he suggests that worms are derived from 'seeds'. He also draws *Taenia saginata*, but calls it *T. solium*, and describes *Diphyllobothrium latum*
1766	Palas realizes that *Echinococcus* cysts are tapeworm larvae
1770	Mongin describes *Loa loa* and the clinical features of loiasis
1793	Chisholm observes transmission of *Dracunculus medinensis*
1808–10	Rudolphi publishes his text *Entozoorum, sive verminum intestinalium, historia naturalis*, regarded as the first textbook on helminthology.
1819	Bremser describes *Enterobius vermicularius*
1819	Rudolphi describes the larvae of *Dracunculus medinensis*
1833	Hilton finds but does not describe *Trichinella spiralis* in human muscle
1835	Paget discovers and Owen reports on the larvae of *Trichinella spiralis* in human muscle
1843	Dubini recognizes the hookworm *Ancylostoma duodenale*
1843	Gruby and Delafond find microfilariae in blood of dogs
1843	Busk discovers *Fasciolopsis buski*
1846	Leidy describes *Trichinella spiralis* in pig muscle
1847	Fujinami describes Katayama disease caused by *Schistosoma japonicum*
1850	Bilharz discovers *Schistosoma haematobium*
1853	von Siebold describes *Echinococcus granulosus* tapeworms in dogs fed with hydatid cysts from sheep

(*Continued over*)

Table 1 *Important events in the history of our knowledge and understanding of parasitic worms.* *(Continued)*

Date	Event
1855	Küchenmeister demonstrates that *Taenia solium* infections are acquired by eating pork
1859	Virchow finds adult worms of *Trichinella spiralis* in a dog fed on infected muscle
1863	Bastian gives a detailed description of *Dracunculus medinensis*
1863	Demarquay finds microfilariae of *Wuchereria bancrofti* in fluid from a scrotal tumor
1863	Naunyn infects dogs with *Echinococcus* hydatid cysts from a human
1863	Cobbold suggests that snails might be the intermediate hosts of schistosomes
1864–9	Cobbold's book *Entozoa* is published
1864	Harley suggests that snails might be the intermediate hosts of schistosomes
1867	Leuckart describes life cycle of *Echinococcus granulosus*
1868	Wucherer finds microfilariae of *Wuchereria bancrofti* in the urine of a patient with hematuria
1869	Fedchenko finds *Dracunculus medinensis* in *Cyclops*
1872	Lewis sees microfilariae of *Wuchereria bancrofti* in human blood
1874	McConnell describes *Clonorchis sinensis*
1875	O'Neill discovers microfilariae of *Onchocerca volvulus* in skin nodules
1876	Normand discovers larvae and adults of *Strongyloides stercoralis*
1876	Joseph Bancroft finds and recognizes adult *Wuchereria bancrofti* worms
1877	Manson demonstrates that *Wuchereria bancrofti* is transmitted by mosquitoes
1877	Bavay describes *Strongyloides stercoralis* larvae and adult worms
1877	Perroncito establishes the bovine source of *Taenia saginata* infections
1879	Perroncito realizes that conditions in mines favor the development of hookworm larvae
1879	Ringer discovers *Paragonimus westermani*
1881	Manson suggests that *Paragonimus westermani* develops in a snail
1881	Leuckart and Thomas independently describe the life cycle of *Fasciola hepatica*
1881	Braun finds larvae of *Diphyllobothrium latum* in fish and induces infections in dogs
1893	Manson reports on the finding of adult *Onchocerca volvulus* worms
1890	Mackenzie finds larvae of *Loa loa*
1895	Argyll-Robertson suggests that *Loa loa* is transmitted by blood-sucking insects
1900	Low, acting on a suggestion by Bancroft, demonstrates microfilariae in mosquito mouthparts and confirms transmission through bite of mosquito
1904	Katsurada describes *Schistosoma japonicum* from a cat
1904	Fujinami finds *Schistosoma japonicum* in a human
1905	Looss elucidates the life cycle of *Ancylostoma duodenale*
1912	Leiper demonstrates transmission of *Loa loa* by flies of the genus *Chrysops*
1913	Turkhud completes the life cycle of *Dracunculus medinensis*
1914	Miyairi and Suzuki describe the life cycle of *Schistosoma japonicum* in snails
1914	Leiper distinguishes between *Schistosoma mansoni* and *S. haematobium* and identifies their snail intermediate hosts
1915	Kobayashi realizes that *Clonorchis sinensis* uses a fish host
1917	Janicki and Rosen independently implicate copepods and fish in the life cycle of *Diphyllobothrium latum*
1922	Koino describes the life cycle of *Ascaris lumbricoides*
1926	Blacklock elucidates the life cycle of *Onchocerca volvulus* in blackflies
1927	Lichtenstein and Brug recognize *Brugia malayi*

References are given in the text and in Grove (1990). Note that the dates of particular discoveries do not always coincide with the dates of publications. This is because in the 19th century and earlier, scientists often made their findings known at meetings or in letters before the publication of the definitive paper. In some cases the reference refers to a later and fuller report. Some of the earlier dates are very approximate.

Cobbold, Richard Owen, and Gottlob Küchenmeister. Although the discovery was made by Paget, much of the credit has been attributed to Owen who not only wrote the definitive report (Owen 1835) but also played down Paget's role in the discovery. The adult worm itself was discovered by Rudolph Virchow and Friedrich Zenker and it was the latter who finally recognized the clinical significance of the infection and realized that humans became infected by eating uncooked pork (see Grove 1990; Bundy and Michael 1996).

HOOKWORMS AND HOOKWORM INFECTION

Human hookworm infections caused by *Ancylostoma duodenale* and *Necator americanus*, the former originating in Asia and the latter in Africa, have been asso-

ciated with humans for over 5 000 years (Hoeppli 1959). Hookworms reached America before the 5th century BC and larvae have been found in coprolites dating from this period (Ferreira et al. 1980). Hookworm disease has been recognized since the earliest records began and the Egyptian papyrus of 1500 BC, the works of Hippocrates in the 5th century BC, and Avicenna in the 10th century all give accurate descriptions of the disease; its history has been reviewed by Foster (1965), Grove (1990), and Ball (1996). Adult *A. duodenale* worms were first recognized by Angelo Dubini in 1843 (Dubini 1843) and credit for the discovery that humans become infected through the skin goes to Arthur Looss who accidentally infected himself and realized that the infection begins when larvae in the soil penetrate the skin, usually of the foot (Looss 1898).

The connection between the presence of worms and hookworm disease was established in 1854 by Wilhelm Griesinger (Griesinger 1854). The clinical signs of hookworm infection – anemia, greenish-yellow pallor, and lassitude – had been observed by Hippocrates and his followers and many early physicians (see Grove 1990) and associated with miners, but it was not until 1879 that Edoardo Perroncito, working with miners in the St Gothard tunnel, realized that the conditions in mines favor the development of the larval stages (Perroncito 1880). The importance of hookworm infections in the USA in the early years of the 20th century led to the establishment of a number of Schools of Public Health and eventually to the creation of the World Health Organization (Ettling 1990).

STRONGYLOIDES AND STRONGYLOIDIASIS

Strongyloidiasis is caused by two species of intestinal nematodes, of which *Strongyloides stercoralis* is the more common and important species. The life cycle involves both parasitic and free-living generations. Parthenogenic female worms lay eggs that hatch within the host and the larvae that are passed out in the feces adopt a free-living existence in the soil from which they penetrate the skin of a new host. Alternatively, the larvae can mature to the infective stage in feces on the skin and reinfect the host through the skin, or mature to the infective stage without leaving the gut and penetrate the gut wall. It is not surprising, given the absence of eggs and confusion with other free-living species of nematodes, that *S. stercoralis* was not recognized until 1876 when both the larvae and the disease, strongyloidiasis, were discovered by Louis Normand who later also found the adult worms and sent them for identification to Arthur Bavay who realized what they were and described them (Bavay 1877). In 1883 Rudolf Leuckart described the alternation of generations involving both parasitic and free-living phases (Leuckart 1883). The discovery that infection with *Strongyloides* occurred through the skin was made by Paul Van Durme based on the work of Looss mentioned above, who had shown that *A. duodenale* infects its host in this way (Van Durme 1901–1902). However, Van Durme was probably working with the other species, *S. fuelleborni* (see Grove 1990), and the mode of infection by *S. stercoralis* was established by Looss who infected himself by putting larvae on his skin and later detecting larvae in his feces (Looss 1905). The phenomenon of autoinfection was described by Friedrich Fülleborn, working with dogs in Hamburg in 1914 (Fülleborn 1914). For nearly a century *S. stercoralis* received little attention, until it was realized that it could cause disseminated infections in immunosuppressed patients, including those infected with the human T-lymphocyte virus type 1 (HTLV-1); although at one time thought to be implicated, *S. stercoralis* is no longer regarded as a major concomitant of acquired immunodeficiency syndrome (AIDS) (see Gutierrez 2000).

LYMPHATIC FILARIASIS

Lymphatic filariasis is caused by infection with the nematode worms *Wuchereria bancrofti*, *Brugia malayi*, and *B. timori*, which are transmitted by mosquitoes. The discovery of the life cycle by Patrick Manson in 1877 is widely regarded as the most significant discovery in tropical medicine, with implications that reached far beyond helminthology into such diverse areas as malaria and the arboviruses. The massive swellings of the limbs associated with lymphatic filariasis cannot have gone unnoticed by our early ancestors, and descriptions of what was almost certainly this disease date back to 2000 BC in Egypt and to Nok sculptures of the Sudan and West Africa from 500 AD (see Grove 1990; Nelson 1996). The larval stages of the filarial worms, microfilariae, were first seen in the blood of dogs in 1843 (Gruby and Delafond 1843) and in humans by Demarquay (1863). This latter discovery attracted the attention of a number of eminent parasitologists, including Wilhelm Greisinger, Theodor Bilharz, and Otto Wucherer but it was a relatively unknown Scottish clinician, Timothy Lewis, who realized that the worms were associated with filariasis (Lewis 1872). The mode of transmission remained a mystery until Patrick Manson discovered that the mosquito was involved (Manson 1878).

The story of Manson's discoveries has been told many times (see Manson-Bahr 1962; Foster 1965; Service and Wilmott 1978; Chernin 1983; Grove 1990; Eldridge 1992; Nelson 1996). Manson, then working in Amoy in China, found microfilariae in the blood of dogs and humans; he hypothesized that these parasites in the blood might be transmitted by bloodsucking insects. Accordingly, he fed mosquitoes on the blood of his gardener, who was harboring the parasites, and subsequently was able to detect larval stages in the mosquitoes (Manson 1878). Manson, probably prompted by Fedchenko's discovery of the life cycle of *Dracunculus medinensis* (see below),

mistakenly believed that the parasites escaped from the mosquito into water and that human infections were acquired through contact with contaminated water. The actual mode of transmission, through the bite of a mosquito, was established only when suggestions by the Australian parasitologist, Thomas Bancroft, were followed up by Manson's assistant George Carmichael Low (Low 1900). Manson was instrumental in the foundation of the London School of Hygiene and Tropical Medicine in 1899 and the Royal Society of Tropical Medicine and Hygiene in London in 1907.

ONCHOCERCA AND ONCHOCERCIASIS

The history of onchocerciasis, or river blindness, caused by the nematode worm *Onchocerca volvulus*, is a relatively short one and there are few reliable early records. This is partly because there are so many causes of blindness in the tropics with which this condition can be confused. Accounts of the history of onchocerciasis are given by Grove (1990) and Muller (1996b). The skin lesions associated with this infection were well known in West Africa and called 'craw craw' by the time John O'Neill first identified nematode larvae in the lesions of those suffering from this condition in 1875 (O'Neill 1875). Adult worms were not seen until some years later when Leuckart received specimens from a German doctor in Ghana and sent them to Manson who, with due acknowledgements, described them in *Davidson's hygiene and diseases of warm climates* (Manson 1893).

For a number of years, this parasite was considered to be a rare curiosity until the connection between the worm and the skin lesions was made by Rodolfo Robles in Central America (Robles 1917). Robles was also the first person to suggest that blackflies might be involved in the transmission of the infection but it was not until 1923–1926 that Donald Breadalbane Blacklock demonstrated conclusively that blackflies were indeed the vectors (Blacklock 1926). In 1928, there came the first report of microfilariae in histological sections of the eyes of blind individuals (Ochoterena 1928) and between 1928 and 1935 a flurry of activity clearly established the role of *Onchocerca* infection as a cause of blindness (see Grove 1990). The 20th century has been one of triumph over this disease, first with the use of insecticides to control the blackfly larvae and later with the development and free distribution of a very effective drug, ivermectin, making the eradication of onchocerciasis a real possibility.

LOIASIS

Loa loa, the nematode that causes loiasis, is a large worm that occasionally passes through the eye and must have been recognized from the earliest times. There are few early records but there is no doubt that Huighen van Linschoten became aware of this worm during the course of his researches into Guinea worm at the end of the 16th century (van Linschoten 1610). The adult worm was first seen by a French surgeon, Mongin, in 1770 (Mongin 1770) and the microfilariae were recognized in 1890 by Stephen Mackenzie who referred his material to Patrick Manson (see Manson 1891). The mode of transmission remained a mystery until 1895 when, basing his ideas on Manson's earlier work on lymphatic filariasis, Douglas Argyll-Robertson predicted that the vector would be a bloodsucking insect but failed to find any parasites in his suspected insect hosts (Argyll-Robertson 1895). In 1912 Robert Leiper threw the list of possible vectors wide open and conclusively demonstrated that the vectors were actually tabanid flies belonging to the genus *Chrysops* (Leiper 1913). One of the signs of loiasis is the presence of swellings, known as Calabar swellings, particularly on the arms and legs. Argyll-Robertson suspected that they were caused by the worm and this was eventually accepted by Patrick Manson who was unsure as to whether the swellings were caused by the blockage of lymphatics or as a result of a pathological reaction to some product of the worm (Manson 1910).

DRACUNCULUS AND DRACUNCULIASIS (GUINEA WORM DISEASE)

Dracunculiasis, caused by the nematode *Dracunculus medinensis*, is the only parasitic infection of which a good description is given in the Bible; most observers agree that the 'fiery serpents' that afflicted the children of Israel in the region of the Red Sea between 1300 and 1234 BC were dracunculus worms (The Bible, Numbers 21, Verse 6; Foster 1965). There are also numerous records of this worm in second millennium papyri from Egypt; writings from Mesopotamia in the 7th century BC; and later records by Greek, Roman, and Arabic physicians (see Grove 1990; Tayeh 1996). One of the best descriptions is that by Avicenna in his book *Al canon fe al tib*. Avicenna recognized that this was a worm and not a rotten vein, as had previously been maintained (hence the old name 'Medina vein'). The presence of the worm in the leg was formally recognized by Thomas Herbert in 1634 (Herbert 1634). Throughout the 18th and early 19th centuries the conviction strengthened that dracunculiasis was caused by the worm *D. medinensis* (listed as *Gordius medinensis* by Linnaeus in 1758) and that infection was acquired through drinking water as suggested by the Dutch navigator Huighen van Linschoten in 1610 (van Linschoten 1610). On the other hand, George Busk (Busk 1846) and H. J. Carter (Carter 1855) argued that the infection could be acquired through the skin. The actual life cycle was unravelled by a Russian scientist, Aleksej Fedchenko, who suspected that water fleas, *Cyclops*, were involved and that infection was acquired by accidentally consuming these invertebrates, but was unable to induce infections in experimental animals by feeding them infected water fleas (Fedchenko 1870). It was not

until 1905 that Robert Leiper demonstrated that *Dracunculus* larvae could survive in digestive juices (Leiper 1906) and the whole life cycle was finally elaborated by Dyneshvar Turkhud in 1913 (Turkhud 1914). The 20th century was one of considerable success in controlling this infection, which is now well on the way to being eradicated.

SCHISTOSOMES AND SCHISTOSOMIASIS

Human schistosomiasis, or bilharzia, affects between 200 and 300 million people and is caused by several species of *Schistosoma* each giving rise to a characteristic form of the disease. Calcified eggs of *Schistosoma haematobium*, the cause of urinary schistosomiasis, have been found in Egyptian mummies dating from 1250 to 1000 BC (Contis and David 1996) providing direct evidence that these schistosomes were present in ancient Egypt. The most obvious sign of urinary schistosomiasis is blood in the urine, and this cannot have gone unobserved by the ancient Egyptians. Inevitably there have been numerous attempts to find descriptions of this condition in the medical papyri and many historians have described the disease as 'aaa' recorded in over 50 early papyri, including the *Papyrus Ebers*. In some papyri, 'aaa' occurs together with the initial hieroglyph interpreted as a penis discharging blood, suggesting schistomiasis haematobia (Ebbell 1937). This interpretation is widely quoted in historical and parasitological textbooks but no passages from the papyri link 'aaa' with the bladder or urine and the discharge from the penis might equally represent semen and not blood. This subject is discussed by Nunn and Tapp (2000), who abandon 'aaa' as a possible ancient Egyptian word for schistosomiasis. However, as schistosomiasis was almost certainly common and widespread in ancient Egypt, it is curious that the Egyptians did not have a word for it unless it was so common that it was ignored. It should be mentioned here that there have been a number of other suggestions as to what 'aaa' might be, including hookworm infection.

The worm itself, *S. haematobium*, was first described by Theodor Bilharz in 1851 and the popular name for all forms of schistosomiasis, 'bilharzia,' now honours his discovery (Bilharz and von Siebold 1852–53). The connection with the urinary disease was made a year later by Bilharz working with Wilhelm Griesinger (Bilharz 1853). The search for the intermediate stages in the life cycle of *S. haematobium* took a long time. A number of experienced parasitologists, including Arthur Looss, Prospero Sonsino, and Thomas Cobbold, working at the end of the 19th century, all failed to infect snails and it was not until 1915 that Leiper demonstrated the complete life cycle in the snail host (Leiper 1916).

Our knowledge of the history of intestinal schistosomiasis, caused by *S. mansoni*, dates back to conclusions reached by Manson in 1902 that there were two species of *Schistosoma* in humans (Manson 1902). At the time this was not universally accepted and it was Leiper who firmly established the existence of *S. mansoni* as a separate species in 1915 (Leiper 1916).

The third important form of schistosomiasis, Katayama disease, caused by *S. japonicum*, was first recognized by Akira Fujinami in 1847 in a report that did not become available until 1909 (Fujinami and Nakamura 1909). The worm itself was discovered by Fujiro Katsurada in 1904 (Katsurada 1904). Development in the snail host was described by Miyairi and Suzuki (1913) 2 years before Leiper independently described the life cycle of *S. haematobium*.

The history of such an important disease as schistosomiasis involves a great number of observations, events, and individuals, and a detailed account of the history is given by Grove (1990). There are shorter accounts by Hoeppli (1959), Foster (1965), and Goodwin (1996a). A bibliography covering the early history of schistosomiasis is given by Warren (1973) and there is an excellent account of schistosomiasis in the context of British and American imperialism by Farley (1991).

LIVER AND LUNG FLUKES

Several flatworms or flukes, probably over 100 as adults or larvae, infect humans, of which the most important are *Paragonimus westermani*, causing paragonimiasis; *Clonorchis sinensis*, causing clonorchiasis; and *Opisthorchis* spp., causing opisthorchiasis. Virtually all the important discoveries about the parasites themselves were made over a period of less than 45 years, between 1874 and 1918, and all were based on observations that had been made on other parasitic flukes such as *Fasciola hepatica* in sheep and others of zoological rather than medical interest. The various discoveries were made by a large number of people and often reported in obscure publications, and no attempt will be made here to list the individual achievements; for this the reader is referred to Grove (1990) and Muller (1996a).

The histories of these infections as diseases begin with the discovery of the worms and continue with the elaboration of the various life cycles. The adult worm of *P. westermani* was discovered in the lungs of a human in Taiwan in 1879 by B.S. Ringer who wrote to Manson who later described his find (see Manson 1881). The presence of eggs in the sputum was recognized independently by Erwin von Baelz in 1880 (von Baelz 1880) and by Manson in 1881 who, having read Ringer's report, realized the connection with the worms he had seen and postulated that a snail might act as an intermediate host (see Manson 1881). A number of Japanese workers, including Koan Nakagawa, Sadamu Yokogawa, Harujiro Kobayashi, and Keinosuke Miyairi, reported on the whole life cycle in the snail *Semisulcospira* between 1916 and 1922 (see Grove 1990).

The human liver fluke, *C. sinensis*, was first recognized by James McConnell in 1875 (McConnell 1875). The

whole life cycle remained a puzzle until Kobayashi discovered that there was a second intermediate host, a fish (Kobayashi 1915), and the snail host was discovered by Masatomo Muto in 1918 (Muto 1918). Kobayashi's discovery that the second intermediate host could be an important food fish had an immediate impact on the control of this infection.

The first records of *Opisthorchis* adult worms in humans were made by Konstantin Wingradoff (1892) and the snail and fish hosts were described by Hans Vogel (1934).

CESTODES AND CESTODIASIS

Humans harbor about 55 species of tapeworms, about 40 adult and 15 larval stages. The most important are the adults of *Diphyllobothrium latum* (the broad tapeworm), *Taenia solium* (the pork tapeworm), *T. saginata* (the beef tapeworm), and the larval stages of the dog tapeworm, *Echinococcus granulosus*. The large size of the adult worms and their common occurrence attracted the attention of all the major medical writers including the authors of the *Papyrus Ebers* and the *Corpus Hippocratorum* and physicians such as Celsus and Avicenna.

It is generally held that the broad tapeworm *D. latum* was first recognized by Felix Plater (sometimes spelled Platter) at the beginning of the 17th century (see Foster 1965; Grove 1990). By the middle of the 18th century it was apparent that individuals harboring *D. latum* were those whose diet was mainly fish, but it was not until the life cycles of other tapeworms of zoological interest had been elaborated that further progress became possible. The existence of three hosts in the life cycle of *D. latum* (human, fish, and copepod) confused the issue until 1917 when Janicki and Rosen independently worked out the whole of the life cycle (Janicki and Rosen 1917). Plater had already provided an excellent description of the disease, and the only significant subsequent discovery was made in 1948 when it was realized that this worm has an affinity for vitamin B_{12}, thus accounting for the pernicious anemia associated with this infection (see von Bonsdorff 1977).

The scientific study of the taeniid tapeworms can be traced to the work of Edward Tyson who, in the late 17th century, studied not only the tapeworms of humans but also those of dogs and other animals. This gave him the opportunity to recognize the 'head' (scolex) of a tapeworm for the first time, to describe the anatomy and physiology of the adult worms, and to lay the foundations for our knowledge of the biology of the taeniid tapeworms of humans (Tyson 1683). Although the distinction between broad and taeniid tapeworms had been recognized by the 17th century, the existence of two species of *Taenia* in humans presented problems because, even to the trained eye, the distinctions between *T. solium* and *T. saginata* are not obvious. This led to confusion between the two worms until a century after the work of Tyson when, in 1782, Johann Goeze noted the similarities between the heads of tapeworms in humans and pigs (Goeze 1782). It was not until 1855 that Gottlob Küchenmeister demonstrated experimentally that eating infected pork gave rise to tapeworms in humans (Küchenmeister 1855) although the presence of cysts in pork had been noted throughout recorded history and is mentioned by Aristotle in the 4th century BC, Hippocrates, and Galen (see Foster 1965; Grove 1990). It has been suggested that, even before these discoveries, people had long been aware of the dangers of infected pork and that this accounted for the Jewish and Islamic prohibitions on the consumption of pork (Küchenmeister 1857) but there is no real evidence for this and the same arguments have been put forward for *Trichinella spiralis*.

The history of our knowledge of *T. saginata* parallels that of *T. solium*, and Goeze and Küchenmeister are credited with recognizing the differences between the two species of *Taenia* in humans. Several years after the implication of pigs as the intermediate hosts of *T. solium*, J.H. Oliver noted tapeworm infections in individuals who had eaten 'measly' beef (Oliver 1871) and the role of cattle as intermediate hosts of *T. saginata* was confirmed in a more controlled experiment in 1877 (Perroncito 1877). Together with observations on the pork tapeworm, these discoveries had a massive impact on the control of tapeworm infections in humans, as they led to a restriction of the amount of infected meat consumed by humans.

Humans are also host to two important kinds of larval tapeworm, cysticerci of the pork tapeworm *T. solium* and hydatid cysts of the dog tapeworm *E. granulosus*. The demonstration of the life cycle of *T. solium* threw new light on the nature of cysticercosis, and it was soon apparent that humans could become infected with the larval stages of *T. solium* when they ingested eggs. This made humans, in effect, dead-end intermediate hosts for this parasite, which also used humans as its definitive hosts. Although, for ethical reasons, the conclusive experiments could not be carried out, by the middle of the 19th century various experiments with animals and observations on humans had established without doubt that cysticercosis was caused by the ingestion of the eggs of *T. solium* (Küchenmeister 1860).

Infections with the larval stages of the dog tapeworm *E. granulosus* cause hydatid disease in humans. These cysts have been recognized from the earliest times and there are accurate descriptions by Hippocrates and Galen among others (see Grove 1990) but it was not until 1684 that Redi recognized the parasitic nature of these cysts (Redi 1684). Pierre Pallas was the first to suggest that these cysts were the larval stages of tapeworms (Pallas 1766) and in 1853 Carl von Siebold demonstrated that echinococcus cysts from sheep gave rise to adult tapeworms when fed to dogs (von Siebold 1853). The whole story was completed in

1863 when Bernhard Naunyn found adult tapeworms in dogs fed with hydatid cysts from a human (Naunyn 1863).

PROTOZOA AND PROTOZOAL INFECTIONS

Discovery of the organisms

Because of their small size, it was not possible to see the unicellular eukaryotic organisms we know as protozoa until the invention of the microscope and Antony van Leeuwenhoek's observations towards the end of the 17th century (Dobell 1960). All commentators agree that the first person to see a parasitic protozoan was Leeuwenhoek, who observed *Giardia* in his own stools. His written descriptions and his clinical observations leave little doubt that this flagellate is indeed the organism that he saw (Dobell 1960). Leeuwenhoek also described, very accurately, a number of other protozoa including flagellates and ciliates in frogs. The protozoa were recognized as a phylum of the animal kingdom a century later (Müller 1786) but it was not until over 140 years after Leeuwenhoek's observations that other parasitic protozoa were described and these were the large and conspicuous gregarines of insects (Dufour 1828), the beloved introduction to parasitic protozoology of generations of parasitologists. Among the conspicuous parasites in the blood are the trypanosomes, and the first to be recognized was from the blood of a fish (Valentin 1841); it is interesting to note that it was more than 50 years before similar parasites were seen in humans. The first associations between blood parasites and disease were those recorded by Griffiths Evans, who found trypanosomes in the blood of horses suffering from surra (Evans 1881). David Bruce found similar organisms in cattle, suffering from nagana, and dogs in 1894–7 (see Bruce 1915). Amebae are also conspicuous protozoa and those in humans were first seen in 1849 by Gros who recognized the nonpathogenic *Entamoeba gingivalis* from the mouth (see Dobell 1919); the pathogenic *E. histolytica* was recognized for the first time by Alexandrovitch Lösch in 1875 (Lösch 1875).

The detection of protozoa living in red blood cells was not possible until the development of adequate staining techniques; the first to be seen were malaria parasites by Charles Laveran in 1880 (Laveran 1880); *Babesia* in cattle by Theobald Smith and Frederick Kilbourne in 1893 (Smith and Kilbourne 1893); and *Theileria* in cattle by Charles Lounsbury in 1904 (Lounsbury 1904).

Leishmania parasites were discovered independently by P.F. Borovsky in 1898, William Leishman in 1903, Charles Donovan in 1903, and James Homer Wright in 1903. The first leishmania parasites associated with New World leishmaniasis were discovered by Gaspar Vianna in 1911.

The remaining important protozoan parasites of humans were not detected until the beginning of the 20th century when, in a flurry of activity, *Trypanosoma cruzi* was identified as the cause of the condition that is now called Chagas disease (Chagas 1909). In a remarkable discovery that was to have much wider implications, *Toxoplasma gondii*, a parasite with the widest known host range including humans, was found in an obscure mammal, the gundi, by Charles Nicolle and Louis Manceaux in 1909.

Table 2 lists some of the most important events in our knowledge and understanding of parasitic protozoa. Note that the considerable activity that occurred during the second half of the 19th century mirrors what was also being done in the field of helminthology.

AMOEBAE AND AMOEBIASIS

Humans harbor nine species of intestinal amoebae of which only one, *Entamoeba histolytica*, is a pathogen. *E. histolytica* causes two forms of the same disease: amoebic dysentery, resulting from the invasion of the gut wall, and hepatic amoebiasis caused by extra-intestinal amoebae in the liver. There is circumstantial evidence that both forms of the disease were recognized from the earliest times, but there are so many causes of both dysentery and liver disease that these records are open to other interpretations (see Bray 1996). The history of amoebiasis has been described by Dobell (1919), Foster (1965) and Bray (1996). James Annersley (1828) is credited with the first accurate descriptions of both forms of the disease and was the first to suggest the connection between them. From the middle of the 19th century, several workers observed amoebae in the stools of patients with amoebic dysentery but credit for the discovery of *E. histolytica* is now given to Alexandrovitch Lösch (Lösch 1875). The association between the amoeba and liver abscesses was finally determined shortly afterwards when Stephan Kartulis demonstrated amoebae in both intestine and liver (Kartulis 1886). Many workers did not believe that *E. histolytica* could cause disease, as all intestinal amoebae were generally thought to be harmless. It was therefore suggested that humans might harbor two morphologically similar amoebae, one pathogenic and one not (see Dobell 1919). This situation has only been resolved comparatively recently using biochemical techniques that clearly show that there are indeed two species: *E. histolytica*, which can cause disease, and *E. dispar*, which cannot (see Classification and introduction to the parasitic protozoa).

GIARDIA AND GIARDIASIS

Giardia holds a special place in the affection of all protozoologists because the parasite that causes giardiasis, *Giardia duodenalis* (also known as *G. intestinalis* or *G. lamblia*) was the first parasitic protozoan ever to

Table 2 *Important events in our knowledge of parasitic protozoa.*

Date	Event
1681	Leeuwenhoek discovers *Giardia duodenalis* in his own feces
1773	Muller describes *Cercaria tenax* (*Trichomonas tenax*) from human mouth
1786	Müller recognizes Protozoa as a phylum of the Kingdom Animalia
1841	Valentin sees trypanosomes in the blood of fish
1848	Gros describes *Entamoeba gingivalis* from a human mouth
1853–4	Devaine describes *Cercomonas hominis* (*Trichomonas* and *Chilomastix*) from human feces
1857	Nägli describes a microsporidian from silkworms
1859	Lambl describes *Giardia duodenalis*
1870	Lewis describes *Entamoeba coli* from a human
1875	Lösch describes *Entamoeba histolytica*
1878	Lewis describes *Trypanosoma lewisi* from a rat
1879	Leuckart creates the phylum Sporozoa
1880	Laveran sees the malarial parasite *Plasmodium* in human blood
1881	Evans finds trypanosomes in the blood of a horse suffering from surra
1885	Cunningham sees *Leishmania* parasites in cutaneous lesions
1887	Metchnikov recognizes the coccidial nature of the malaria parasites
1891	Nepveu sees African trypanosomes in human blood
1893	Smith and Kilborne describe *Babesia* from cattle and incriminate ticks in its transmission
1894	Bruce sees trypanosomes in the blood of cattle and suggests a connection with tsetse flies
1897	Ross demonstrates the mosquito transmission of malaria parasites
1898	Bignami, Grassi, and Bastianelli describe mosquito stages of human malaria parasites
1898	Borovsky sees *Leishmania* parasites in a cutaneous lesion
1902	Dutton finds *Trypanosoma brucei gambiense* in human blood
1903	Wright describes *Leishmania* from cutaneous lesions
1903	Leishman and Donovan independently describe *Leishmania* from kala azar patients
1904	Bruce suggests that tsetse flies transmit African trypanosomes
1908	Nicolle and Manceaux and Splendore independently discover*Toxoplasma gondii*
1909–12	Chagas discovers *Trypanosoma cruzi*, its role in South American trypanosomiasis and transmission by bugs
1909	Kleine describes the cyclical transmission of trypanosomes
1910	Stevens and Fantham recognize *Trypanosoma brucei gambiense*
1911	Vianna describes *Leishmania braziliensis* in the New World
1912	Brumpt describes the transmission of *Trypanosoma cruzi* via the feces of bugs
1912	Tyzzer describes *Cryptosporidium* from a mouse
1921	Sergent and Sergent show that *Leishmania* parasites are transmitted by sandflies
1937	Wolf and Cowan implicate *Toxoplasma gondii* in human disease
1941	Adler and Ber demonstrate that leishmaniasis is transmitted through the bite of a sandfly
1948	Shortt and Garnham describe liver stages of malaria parasites
1959	Matsubayashi and colleagues describe a human infection with the microsporidian, *Encephalitozoon*
1976	Nime and colleagues and Meisel and colleagues independently describe human infections with *Cryptosporidium*
1969	Hutchison and colleagues describe life cycle of *Toxoplasma gondii*
1979	Ashford finds *Cyclospora* in a human
1982	Krotoski and colleagues discover *Plasmodium* hypnozoites

References are given in the text. Note that the dates of particular discoveries do not always coincide with the dates of publications. This is because in the 19th century and earlier scientists often made their findings known at meetings or in letters before the publication of the definitive paper. In some cases the reference refers to a later and fuller report.

be seen. An account of the history of giardiasis is given by Farthing (1996).

The first good accounts and illustrations of *Giardia* were by Vilém Lambl (1859), but the parasite received little attention until the war of 1914–1918 when troops returning to the UK with diarrhea were found to have, in their feces, *Giardia* cysts which caused similar infections in laboratory animals (Fantham and Porter 1916). In 1921 the distinguished British protozoologist Clifford Dobell suggested that *Giardia* could be a serious pathogen (Dobell 1921) and in 1926 Reginald Miller observed diarrhea and malabsorption in children infected with *Giardia* (Miller 1926). It still took some time before the association between infection with

Giardia and disease became widely recognized, following the detailed studies of Robert Rendtorff who produced unambiguous evidence linking the parasite with disease (Rendtorff 1954).

In the 300 years since *Giardia* was first discovered it has become recognized as a common and serious pathogen worldwide. It is still not known how many species infect humans and what role, if any, is played by reservoir hosts in the epidemiology of the infection.

AFRICAN TRYPANOSOMES AND SLEEPING SICKNESS

The story of African sleeping sickness is told briefly by Hoare (1972) and in more detail by Foster (1965), Nash (1969), Lyons (1992), Williams (1996), and Cox (2004b). The early records of African trypanosomiasis or sleeping sickness are vague. The first definitive accounts are those given by an English naval surgeon, John Atkins, in 1721 (see Atkins 1734) and Thomas Winterbottom, who coined the term 'negro lethargy,' in 1803 (Winterbottom 1803). Many explanations were put forward as causes of sleeping sickness, but the real basis of the disease was not forthcoming until Pasteur had established the germ theory towards the end of the 19th century. The first clues came from observations on surra, a horse disease, and nagana, a wasting disease of cattle. Although trypanosomes had been seen in the blood of fishes, frogs, and mammals several years before, it was not until 1881 that Griffith Evans found trypanosomes in the blood of horses and camels suffering from surra and suggested that the parasites might be the cause of the condition (Evans 1881).

In 1894, David Bruce, a British army surgeon, was sent to Zululand (now part of South Africa) to investigate an outbreak of nagana in cattle. Given the scientific climate of the period, Bruce suspected a bacterial cause but instead found trypanosomes in the blood of diseased cattle; he later demonstrated that these caused nagana in cattle, horses, and dogs. Bruce also noticed that infected cattle had spent some time in the fly-infested 'tsetse belt' and that the disease was similar to that in humans suffering from the 'fly disease' of hunters (Bruce 1895, 1915). Bruce also showed that the infection was acquired from tsetse flies, but mistakenly thought that transmission was purely mechanical.

It was later discovered that the trypanosomes that cause nagana and surra are not the same as those that cause human sleeping sickness. Although organisms that were certainly trypanosomes had been seen in human blood by Gustave Nepveu in 1891 (see Nepveu 1898) it was not until 1902 that Everett Dutton found the trypanosome that causes Gambian or chronic sleeping sickness (*Trypanosoma brucei gambiense*) in humans (Dutton 1902). In 1910 *T. b. rhodesiense*, the cause of Rhodesian or acute sleeping sickness, was described by J.W.W Stephens and Harold Fantham (Stephens and Fantham 1910). The role of the tsetse fly in the transmission of sleeping sickness remained controversial until Friedrich Kleine, a colleague of Robert Koch, demonstrated cyclical transmission, but he mistakenly thought that there was a sexual stage in the life cycle (Kleine 1909).

The persistence of trypanosomes in the blood and the existence of successive waves of parasitemia have attracted the attention of all those who have worked with trypanosomiasis. This phenomenon was described in detail by Ronald Ross and David Thomson in 1911 (Ross and Thompson 1911). The underlying mechanism and the way in which the parasite evades the immune response, now called 'antigenic variation,' were not elaborated until the work of Keith Vickerman in 1969 (Vickerman and Luckins 1969); this discovery precipitated a vast amount of interest in trypanosomes as cells and not only as causes of disease. Other 20th-century investigations have been concerned with refining the early discoveries and establishing the epidemiology of African sleeping sickness, leading to the development of methods for the control of both the human and animal forms of trypanosomiasis and the development of new and effective drugs.

SOUTH AMERICAN TRYPANOSOMIASIS: CHAGAS DISEASE

The earliest records of Chagas disease in South America are from 2 500-year-old mummies that show clear signs of the destructive nature of the disease (Rothammer et al. 1985). There are also a number of possible early written records, but the signs and symptoms of Chagas disease are so vague that it is difficult to know whether or not many of the conditions attributed to this infection are really valid. The early history of Chagas disease is described by Guerra (1970) and Miles (1996) and is passed over here because, from a scientific and medical viewpoint, the history really begins with a remarkable series of discoveries that were made between 1907 and 1912 by Carlos Chagas. Chagas not only discovered the trypanosome that causes the disease but also demonstrated its life cycle in the bugs that transmit it and described the disease which, although it affected millions of people, had until then remained enigmatic. Chagas's discoveries have been extensively described elsewhere (Wenyon 1926; Scott 1939; Guerra 1970; Lewinsohn 1979; Kean et al. 1978; Leonard 1990; Miles 1996). Briefly, Chagas, who was then in charge of an antimalaria campaign in Brazil, noticed that the bugs that infested the poorly constructed houses harbored flagellated protozoa; these could experimentally infect monkeys and guineapigs, in the blood of which a new trypanosome, *Trypanosoma cruzi*, was subsequently detected (Chagas 1909). Chagas suspected that these bugs might also transmit the parasite to humans and confirmed this when he found the trypanosomes in the blood of children

suffering from an acute febrile condition (Chagas 1911). In 1912, Chagas demonstrated that *T. cruzi* was maintained in a number of reservoir hosts (Chagas 1912) thus completing in less than 5 years a cycle of discovery that had taken many years for earlier workers in other fields. The disease that affects some 18 million people now commemorates his name.

One thing that Chagas did not get right was the actual mode of transmission by the bug, as he thought that the trypanosomes were transmitted via the bite of the insect; it was left to Emile Brumpt to demonstrate that transmission was via the fecal route (Brumpt 1912). The links between infection with *T. cruzi* and the various signs of Chagas disease, such as megacolon, megaesophagus, and cardiac failure, were not determined until the work of Fritz Koberle in the 1960s (Koberle 1968). Exactly how the damage to heart and nerves is caused and whether or not there is an autoimmune component are still controversial issues.

LEISHMANIA AND LEISHMANIASIS

Leishmaniasis, caused by several species of *Leishmania*, is transmitted by sandflies and occurs in various forms in both the Old World and New World. Human leishmaniasis was, and still is in some cases, acquired accidentally from naturally infected wild animals. The conspicuous cutaneous lesions have been the subject of numerous records dating back to 2500–1000 BC (see Manson-Bahr 1996). Detailed descriptions of the Old World forms are given by the Arab physicians including Avicenna in the 10th century, and missionaries were well aware of this disease in the New World in the 16th century (see Lainson 1996).

The history of Old World leishmaniasis is described by Hoare (1938), Garnham (1987), and Manson-Bahr (1996). The discovery of the parasite responsible for the Old World cutaneous disease has been a matter of some controversy. There is no doubt that the organism was actually seen in 1885 by David Cunningham (Cunningham 1885) and in 1898 by a Russian military surgeon, P.F. Borovsky (see Hoare 1938), but credit for its discovery is usually given to James Homer Wright (Wright 1903). Credit for the discovery of *Leishmania donovani*, the parasite that causes visceral leishmaniasis (kala azar), goes to William Leishman and Charles Donovan who independently discovered the parasite in the tissues of patients suffering from this condition (Donovan 1903; Leishman 1903). Borovsky's discoveries were unknown to Wright and to Leishman and Donovan, but the names of the two latter workers are commemorated in the popular designation of the intracellular parasites as Leishman–Donovan bodies.

The search for a vector was a long one, partly because of the small size of the sandfly vectors. Although enough epidemiological evidence to incriminate sandflies belonging to the genus *Phlebotomus* had accumulated by the mid 1910s, it was not until 1921 that the experimental proof of transmission to humans from a sandfly was demonstrated by the Sergent brothers, Edouard and Etienne (Sergent et al. 1921). Infection through the bite of a sandfly was not finally demonstrated until 1941 (Adler and Ber 1941).

Leishmaniasis also occurs in the New World; the disfiguring conditions caused have been recognized in sculptures since the 5th century and in the writings of the Spanish missionaries in the 16th century (see Lainson 1996). Until 1911, it was thought that the New World forms of leishmaniasis were the same as those of the Old World, but in that year Gaspar Vianna found that the parasites in South America differed from those in Africa and India and created a new species, *Leishmania braziliensis* (Vianna 1911). Since then a number of other species, causing cutaneous and mucocutaneous leishmaniasis, unique to the New World have been described suggesting that this is where they emerged independently (see New World leishmaniasis). There is, however, some controversy about the status of New World visceral leishmaniasis which was once thought to be caused by *L. donovani*, a species imported from the Old World possibly with the Spanish military and missionaries. This parasite has long been regarded as a separate species, *L. chagasi*, named in honor of the great Brazilian parasitologist Carlos Chagas, but the validity of *L. chagasi* as a New World species has been challenged by biochemical and molecular studies and it is now thought to be *L. infantum*, a species related to *L. donovani*, and thus of Old World origin (Maurício et al. 2000).

Following the discovery of the sandfly transmission of Old World leishmaniasis, the vectors in the Old World were also thought to belong to the same genus, *Phlebotomus*, but in 1922 it was discovered that the genus involved was actually *Lutzomyia*. Over the last two decades the complex pattern of species of parasite, vector, reservoir host, and disease has been painstakingly elaborated by Ralph Lainson and his colleagues (see Lainson 1996 and New World leishmaniasis).

MALARIA

Malaria ranks among the most important infectious diseases in the world. Its history extends into antiquity and has been reviewed many times by, for example, Garnham (1966), Harrison (1978), Bruce-Chwatt (1985, 1988), McGregor (1996), Nye and Gibson (1997), Dobson (1999), and Poser and Bruyn (1999). Malaria almost certainly evolved with humans during our evolution from our primate ancestors; similar parasites are common in monkeys and apes. The disease probably originated in Africa and spread with human migrations, first throughout the tropics, subtropics, and temperate regions of the Old World and then to the New World with explorers, missionaries, and slaves. The

periodic fevers of malaria are characteristic and are mentioned in the records of every civilized society from China in 2700 BC, through the writings of Greek, Roman, Assyrian, Indian, Arabic, and European physicians up to the 19th century. The earliest detailed accounts are those of Hippocrates in the 5th century BC, and for the next 700 years much of what we know about malaria relates to the disease in Greece, Italy, and throughout the Roman Empire. Thereafter, references to malaria become commonplace in Europe and elsewhere.

The science of malariology could not take off until the end of the 19th century, with the establishment of the germ theory and the birth of microbiology; a start was then made in earnest to discover the cause of the disease that was threatening many parts of the European empires. The story of the discovery of the malaria parasite and its mode of transmission is one of the most exciting in the history of infectious diseases and, like all good stories, is full of triumphs, disappointments, and rivalries (see McGregor 1996).

In 1880, a French army surgeon, Charles Laveran, looking for a bacterial cause of malaria, found and described malarial parasites in human blood and the parasite was immediately causally linked with the disease (Laveran 1880). The mode of transmission was not at all clear and numerous suggestions were put forward, none of which stood up to any detailed analysis. The actual incrimination of the mosquito as a vector was largely due to the intuition of Patrick Manson. In 1877 Manson had demonstrated the mosquito transmission of lymphatic filariasis (Manson 1878), in 1893 Smith and Kilbourne had shown that ticks transmit piroplasms (Smith and Kilbourne 1893), and in 1894 Bruce had implicated tsetse flies in the transmission of African trypanosomiasis (Bruce 1895). Thus, it was evident to Manson that a vector might be involved in the transmission of malaria and he postulated that it could be a mosquito (Manson 1894). Manson was unable to undertake this investigation himself, and secured the services of Ronald Ross, an army surgeon working in India. After several false starts using the wrong kinds of mosquito, *Culex* and *Aedes* instead of *Anopheles*, Ross, who had already demonstrated that bird malaria parasites developed in mosquitoes, found developing parasites in a mosquito fed on the blood of a patient suffering from malaria (Ross 1897). The rest of the life cycle in the mosquito was worked out by the Italian scientists Amico Bignami, Battista Grassi, and Giovanni Bastianelli (see Bastianelli and Bignami 1900; Fantini 1999). There is considerable controversy about the respective roles of Ross and the Italian workers in the discovery of the life cycle of the malaria parasite in the mosquito, and the arguments have been well rehearsed elsewhere. Nevertheless, most commentators agree that it was Ross who incriminated the mosquito as the vector of malaria parasites in birds and that he and the Italian workers established that this was also the case for the human malaria parasites independently at about the same time (see Dobson 1999; Fantini 1999).

The life cycle in humans, however, remained incompletely understood and nobody knew where the parasites developed during the first 10 days after infection, as they could not be found in the blood. In part this was due to too much reliance on a mistake by the influential German scientist Fritz Schaudinn who, in 1903, described the direct penetration of red blood cells by the infective sporozoites injected by the mosquito (Schaudinn 1903). The question was not resolved until 1947 when Henry Shortt and Cyril Garnham, working in London, showed that a phase of division in the liver preceded the development of parasites in the blood (Shortt and Garnham 1948); thus the whole life cycle had taken over 50 years to elucidate. There remained one further problem; what caused the long prepatent period between infection and the appearance and reappearance of parasites in the blood seen in some temperate strains of *P. vivax*? This led to the discovery in 1982 of dormant exoerythrocytic stages, hypnozoites, by Wojciech Krotoski, working with Garnham's team (Krotoski et al. 1982).

The last 50 years have been dominated by the control of the malaria parasite and its vectors by drugs and insecticides and the search for a vaccine. For a fascinating and amusing insight into the problems, solutions, intrigues, and personalities involved, the reader is referred to the popular book *The malaria capers* by Robert Desowitz (Desowitz 1991).

TOXOPLASMA, TOXOPLASMOSIS, AND INFECTIONS CAUSED BY RELATED ORGANISMS

The history of toxoplasmosis is a relatively recent one despite the fact that the organism that causes the disease, *Toxoplasma gondii*, is the most common human parasite world wide and one that infects the widest range of hosts (see Toxoplasmosis). The history of toxoplasmosis has largely escaped the attention of the major reference books, but the basic events are well covered by Dubey and Beattie (1988) and Moulin (1993). *T. gondii* was discovered, largely by accident, by Charles Nicolle while searching for a reservoir host of *Leishmania* in a North African rodent, *Ctenodactylus gondi* (Nicolle and Manceaux 1909). At about the same time, Alfonso Splendore, working in São Paulo, discovered the same parasite in rabbits (Splendore 1909) and subsequently there have been numerous records from mammals and birds both in the wild and in captivity. The association with human disease was not made until 1937 when Arne Wolf and David Cowen reported on a congenital infection (Wolf and Cowen 1937). This report stimulated a vast amount of research, quickly leading to the knowledge that *T. gondii* is actually a very common parasite of humans but rarely causes disease, and that the parasite can cross the placenta and damage the fetus. The life cycle of *T. gondii* remained

elusive until 1970 when William Hutchison and his colleagues demonstrated that this parasite is a stage in the life cycle of a common intestinal coccidian of cats (Hutchison et al. 1970), an observation quickly confirmed by other workers who had been working on this problem at the same time (see Cox 2002).

The parasitological significance of this discovery was that until then it had been assumed that the intestinal coccidians of vertebrates had only one host. The discovery of the *T. gondii* life cycle initiated a massive search for similar phases in the life cycles of other coccidian parasites. As a result, a number of protozoa that had not been properly identified could be classified as stages in the life cycle of poorly understood coccidians that had occasionally been encountered in the intestine and tissues of humans and other animals and in which transmission depends on predator–prey relationships (see *Sarcocystis*). The species that infect humans are *Sarcocystis hominis*, acquired from cattle, and *S. suihominis*, acquired from pigs, and a complex of species collectively known as *S. lindemanni*. There is a detailed account of the nature and discovery of these species by Tadros and Laarman (1982).

CRYPTOSPORIDIUM, *CYCLOSPORA*, AND *ISOSPORA*

Humans also harbor three other species of coccidia, *Cryptosporidium parvum*, *Cyclospora cayetanensis*, and *Isospora belli*, once regarded as rare and accidental curiosities but now identified as possible pathogens in AIDS patients and immunocompromised individuals. All have simple single-host life cycles. *Cryptosporidium parvum* was discovered in 1912 by the American parasitologist Edward Ernest Tyzzer in the gastric glands of laboratory mice in which he had previously found another species, *C. muris* (Tyzzer 1912). The first sporadic human cases were recorded independently in 1976 by Nime and colleagues (Nime et al. 1976) and Meisel and colleagues (Meisel et al. 1976) but from 1981 onwards numerous new cases began to be recognized in AIDS patients. *C. parvum* is not very host-specific, and the source of these infections is probably drinking water contaminated with cattle feces. *Cryptosporidium* infections are now known to be very common and have caused a number of epidemics. There are histories of human cryptosporidiosis by McDonald (1996) and in Dubey et al. (1990).

Cyclospora cayetanensis, another coccidian that is mainly associated with AIDS, was discoved in 1979 by the English parasitologist Richard Ashford who found an unidentified coccidian in patients in Papua New Guinea (Ashford 1979), but it received little attention until 1986 when it was found again in the stools of patients with HIV (Soave et al. 1986). In 1993, this parasite was formally named *Cyclospora cayetanensis* (Ortega et al. 1993) and since then it has been identified as the cause of a number of outbreaks of diarrhea and fatigue in both immunocompetent and immunosuppressed individuals but the reservoir host, if any, is not known.

Isospora belli, the last of this group of parasites, was discovered in 1915 (Woodcock 1915) and is another coccidian frequently found in asymptomatic immunocompetent individuals but is associated with diarrhea in AIDS patients.

MICROSPORIDIANS

Microsporidians are common spore-forming parasites of vertebrates closely related to the Fungi (Cavalier-Smith 1998) but traditionally regarded as parasites. During the 19th century microsporidians attracted considerable attention, mainly as parasites of invertebrates, following the discovery of spores of *Nosma bombycis* by Nägeli in 1857 while investigating an outbreak of a disease called pébrine in the silkworm *Bombyx mori* (Nägeli 1857) and subsequent detailed investigations by Louis Pasteur in 1870 (see Vallery-Radot 1924). In the last decade of the 19th century, and throughout the 20th century, increasing numbers of species of microsporidians were discovered in fish, amphibians, reptiles, birds, and mammals (see Canning and Lom 1986). There have also been several sporadic reports of what might have been human microsporidial infections, but it is difficult to interpret the various structures that have been described as spores. The first human case was probably that of '*Encephalitozoon chagasi*' in a newborn baby in 1927 (Torres 1927) but this cannot be confirmed because the original material has been lost. The parasite named *Encephalitozoon hominis* by Wolf and Cowen (1937) is now known to have been *Toxoplasma gondii*. The first authenticated record of human microsporidiosis was in 1959 when Hisakichi Matsubayashi and his colleagues in Japan found an *Encephalitozoon* sp. in a boy with convulsions (Matsubayashi et al. 1959). Thereafter, there have been increasing numbers of reports of cases of microsporidian infections in humans. In 1985 a new microsporidian, *Enterocytozoon bieneusi*, was found in an AIDS patient (Desportes et al. 1985) since when about 14 species, belonging to seven genera, have been associated with fulminating infections in immunodepressed patients, some with less serious infections in immunocompetent individuals (Canning 2001), and the number of cases, particularly in AIDS patients, continues to rise. Very little is known about the transmission and epidemiology of the microsporidians. There is a detailed account of the microsporidians in

Microsporidiosis.

SUMMARY AND CONCLUSIONS

The history of parasitology is a fascinating one, and parasites have been the subject of some of the most exciting discoveries in the field of medicine. In this chapter, it has not been possible to do more than merely

touch on the major events, each one of which has represented the culmination of years of observation, conjecture, and experimentation. The personalities involved have been among the most eminent of their generations, but the cooperation and competition that existed between them would require a book on its own. The history of parasitology to a large extent reflects the availability of new concepts and techniques; thus each discovery has been the product of its own time and has been possible only because particular individuals have been willing and able to exploit new knowledge as it became accessible. There is more to the history of parasitology than this, because most of the great discoveries were made by individuals who were not looking in the same direction as everybody else. The conviction that diseases arose from decay and the air we breathe held back the discovery of the microbial causes of diseases despite the fact that, with hindsight, all the clues had been there. Had the helminthologists been able to persuade others not only that worms do not arise de novo, but also that they cause disease, the germ theory would have emerged two centuries earlier. The germ theory, with its emphasis on the search for bacterial causes of disease, held back the discovery of the protozoal causes of disease; in another context, it also inhibited a logical approach to nutritional disorders. Those who broke through the barriers of preconceived ideas, no matter how fashionable, were the ones who made the greatest discoveries. The history of 20th-century medicine will pinpoint the mistakes made in the study of AIDS and bovine spongiform encephalopathy (BSE) and will, almost certainly, tell us that our approaches to such subjects as vaccines and drugs were misplaced. For the present, it is widely assumed that all the important discoveries have been made; moreover, the climate of research at the beginning of the 21st century favors large teams working on relatively small projects. It is difficult to imagine that any future discoveries in the field of parasitology will engender the excitement of many of those outlined in this chapter, but there will certainly be new inventions and developments. There will, for example, be new drugs and new vaccines; new species will be described, and molecular techniques will be used to unravel details about both the parasites and the diseases they cause. These developments will bring fame and fortune, membership of learned societies, and possibly Nobel Prizes, but the most important achievements will probably go unsung. The campaign for the eradication of Guinea worm is reaching its final stages, the eradication of river blindness is well on its way, there is now an ambitious program to eradicate lymphatic filariasis and, in many parts of the world, malaria is being controlled by the use of insecticide-impregnated bed nets. These events, which will probably not be mentioned in any publications other than specialized reports, will be much more important to those suffering from these diseases than any other more spectacular discoveries or advances. The future history of parasitology will be, and should be, written in terms of the development of the underprivileged parts of the world that have borne the burden of these diseases for far too long.

PARASITIC DISEASES AND GLOBAL HEALTH

Introduction

This chapter describes the prevalence and overall distribution of parasitic infections in the world, the burden they constitute to the human population, and the costs they represent to individuals and society.

In 1993, life expectancy in the least developed countries of the world was 43 years, compared with 73 years in developed countries. Although life expectancy was projected to increase to 79 years by the year 2000 in developed countries, it was expected to remain less than 60 years in 45 developing countries (WHO 1995a). About 51 million people died in the world in 1993, 39 million of them in the developing countries. Worldwide, communicable diseases were responsible for c. 40 percent of the total number of deaths (20 million). In contrast, 80 percent (16 million) of deaths in developing countries were due to infectious and parasitic diseases (WHO 1995a). Five years later, communicable diseases, including bacterial, viral, parasitic, and zoonotic diseases, still caused 13.3 million (25 percent) of the 53.9 million deaths that occurred in 1998. In that year, communicable diseases were the main cause of death among children aged 0–4 years (63 percent of all deaths), and of premature deaths (48 percent of all deaths) in ages 0–44 years. They were also the main cause of death (45 percent of all deaths) in low-income countries such as those from South East Asia and Africa (WHO 1999). Six diseases were the leading infectious disease killers: acute respiratory infections (including pneumonia and influenza), acquired immune deficiency syndrome (AIDS), diarrheal diseases, tuberculosis, malaria, and measles (WHO 1999). Even in 2001, 19 percent of the 56.554 million deaths that occurred in the world were caused by infectious or parasitic diseases. Lower respiratory tract infection was the main killer (3.871 million deaths), followed by HIV/AIDS (2.866 million), diarrheal diseases (2.001 million), tuberculosis (1.644 million), malaria (1.124 million), and measles (745 thousand deaths) (WHO 2002).

Communicable diseases occur worldwide. Poverty and its accompanying features (lack of sanitation, malnutrition, illiteracy, and overcrowding) all contribute to most of the parasitic diseases of public health importance. Although infectious and parasitic diseases are more significant causes of morbidity and mortality among the poor, no-one is exempt from infection. Internal and external parasites are among the most common pathogens worldwide and anyone can be exposed to them at home or when they travel.

The burden of parasitic diseases

A comprehensive study by the World Bank (1993a) attempted to measure the burden that diseases, as a group or individually, represent in different regions of the world. The measurement took into account both losses from premature death (defined as the difference between the actual age of death and the age at which death would have occurred in a population with a low mortality) and the effects of losses caused by weakened health. The effects of the loss of healthy life were quantified for the diseases listed in the 109 categories

included in the International Classification of Diseases (WHO 1977) and for approximately 95 percent of possible causes of disability (World Bank 1993a). To evaluate losses from illness, the incidence of cases by age, sex and demographic region was estimated and the number of years of healthy life lost was obtained by multiplying the expected duration of the disease by a severity weight that estimated the severity of the disability in comparison with loss of life caused by the illness (World Bank 1993a). The global burden of disease estimated in this manner was quantified using a unit called the disability adjusted life year (DALY), one DALY being defined as the loss of 1 year of healthy life to disease. The relative global burden of a specific disease was estimated by comparing the DALYs lost from different diseases or groups of diseases. In many areas of the world, communicable diseases continue to impose a significant burden that is greater in developing countries than in countries with established market economies. Injuries also cause greater losses in developing countries than in developed countries (Figure 1).

Parasitic diseases contribute heavily to the burden produced by communicable diseases, their contribution being comparable with such common diseases as tuberculosis, sexually transmitted diseases, diseases preventable by vaccination, and acute respiratory infections. Malaria is the parasitic disease responsible for the greatest burden worldwide; in Africa its burden is almost as great as that produced by acute respiratory infections. Worm infections are also a significant burden in Africa and some other regions (Figure 2) (World Bank 1993b).

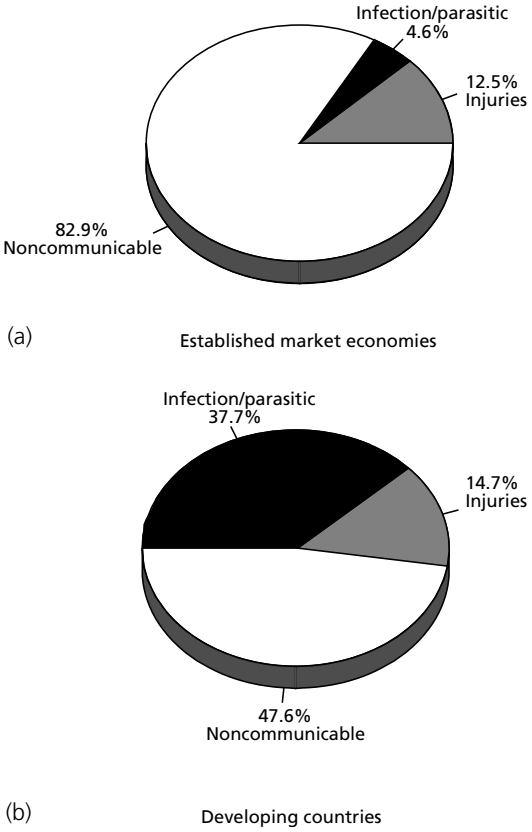

Figure 1 *Percentage distribution of DALYs lost by overall cause in* **(a)** *countries with established market economies and* **(b)** *developing countries (data from World Bank 1993b).*

The burden of infectious diseases, including parasitic infections, is borne mainly by the poorest people in the poorest countries of the world. Parasitic diseases are thus contributing to inequalities that exist both within and between societies (Evans and Jamison 1994). In Figure 3, the DALYs lost as a result of infectious diseases of microbial and viral origin are compared with the losses caused by parasitic diseases in developing countries and in countries with established market economies. Although the burdens produced by diseases of viral or microbial origin are the highest, the burden produced by parasitic diseases is also great (World Bank 1993b). The effects and burdens produced by parasitic diseases vary greatly from region to region. Different parasitic diseases are responsible for the bulk of the burden in different geographical areas; for example, malaria and schistosomiasis are the diseases that cause the highest burden globally, but Chagas disease produces the highest burden in Latin America and the Caribbean (Figure 4).

The burden of different communicable diseases also varies with age (Table 2.1). Among parasitic diseases in 1990, malaria produced the highest burden in children under 5 years of age, and intestinal worms produced the highest burden in children aged 5–14 years (Table 2.1). The situation remained the same in 2001: independent of age, malaria was still the parasitic disease that produced the highest burden among all parasitic diseases (Table 2.2) (WHO 2002).

Disease burdens vary not only with age and geographical region but also among demographic groups. Not surprisingly, a significant proportion of the deaths caused by communicable diseases occurs in developing countries (Tables 2.3 and 2.4) and the individuals at greatest risk are those living in rural areas and in urban squatter settlements. Such people are usually poor and lack adequate housing, safe water supplies, and good waste-disposal systems. Workers involved in mining and timber exploitation are also often exposed to parasitic diseases as an occupational hazard (Rosenfield et al. 1984).

Population movement and parasitic diseases

Population movements have helped to raise awareness of parasites as a worldwide public health problem. In the early 1990s, 500 million people crossed international borders by air, 18–20 million refugees were generated from conflicts and 20–30 million people were displaced

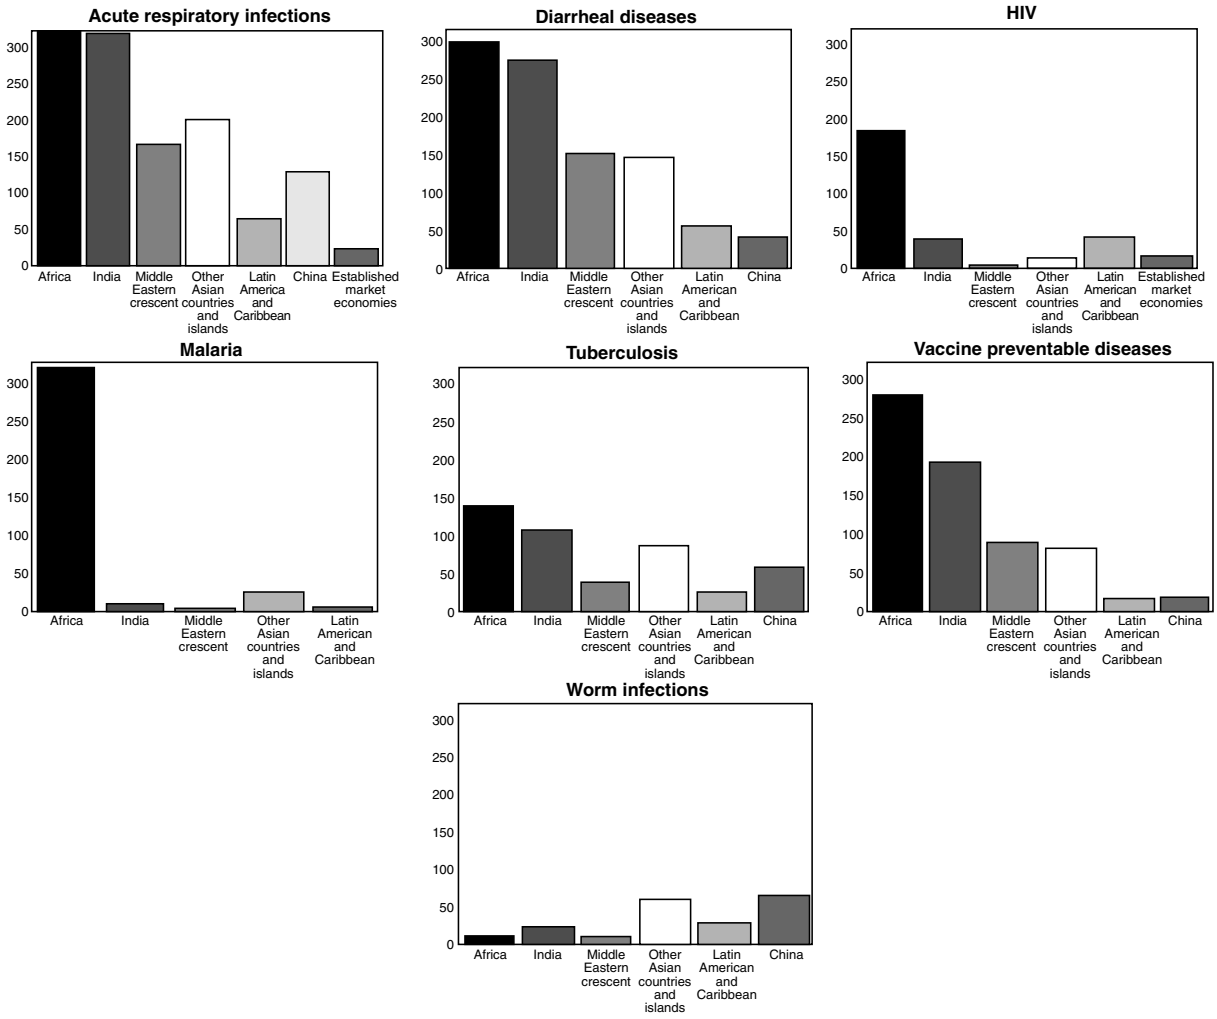

Figure 2 *Distribution of DALYs lost by selected communicable diseases by region, 1990 (hundreds of thousands of DALYs lost) (data from World Bank 1993b).*

for other reasons (Wilson 1995; WHO 1995b). Of the 5.2 billion people in the world, 1 in every 134 was forced to leave their home in 1992 (WHO 1995b) and an estimated 70 million people, mostly from developing countries, work in countries to which they have migrated (Wilson 1995). Many of these people have carried parasites to their new homes, sometimes requiring treatment themselves and sometimes serving as sources of infection to others. As a result of these population shifts, medical personnel in many advanced countries have gained personal experience of parasitic diseases for the first time.

The USA exemplifies the problems faced by the countries with immigrants with intestinal parasites. It is estimated that more than 600 000 immigrants enter the USA each year from countries where intestinal parasites are endemic: Asia, the Middle East, sub-Saharan Africa, Eastern Europe, Latin America, and the Caribbean. At entry, people with parasitic infections may be asymptomatic, and stool examination is not sensitive enough as a screening method for detecting all of those infected. There is, however, a broad-spectrum antiparasitic drug, albendazole, which is safe and effective in eradicating many intestinal worms; it would be possible to screen all immigrants for parasites and to treat those infected or to treat all immigrants presumptively (400 mg of albendazole per day for 5 days). Another possibility would be to do nothing unless the immigrants have symptoms (watchful waiting). Estimates of the costs of these three types of intervention were made, and effectiveness was expressed both in terms of the cost of treatment per DALY averted and in terms of the cost per hospitalization averted. Presumptive treatment of all immigrants at risk for parasitosis, when compared with watchful waiting, would avert at least 870 DALYs, prevent at least 33 deaths and 374 hospitalizations, and save at least US$4.2 million per year. Screening compared with watchful waiting would cost US$159 236 per DALY averted. It was therefore concluded that presumptive treatment of all immigrants at risk of parasitosis would save lives and money, while universal screening and treatment only of those with positive stools,

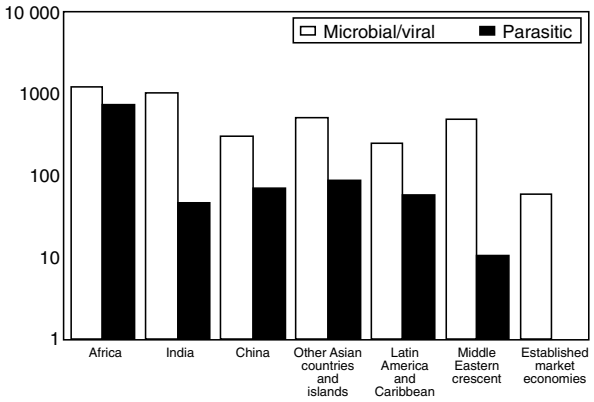

Figure 3 *Burden of disease caused by parasites (including malaria, African and American trypanosomiasis, schistosomiasis, leishmaniasis, filariasis, onchocerciasis, ascariasis, trichuriasis, and hookworm) and by microbial and viral infections (including tuberculosis, sexually transmitted diseases, HIV, diarrheal diseases, pertussis, poliomyelitis, diphtheria, measles, tetanus, meningitis, hepatitis, and acute respiratory infections) by region, 1990 (hundreds of thousands of DALYs lost) (data from World Bank 1993b).*

would save lives but would be less cost-effective (Muennig et al. 1999).

In addition to international migration, many people also migrate between regions of a country; in the last six decades, economic hardship in the rural areas of developing countries has stimulated migration to urban areas within the same country. As a result, c. 45 percent of the world's population now live in cities, and diseases that were traditionally considered to be 'rural' have spread into the cities, usually affecting the most deprived populations. This phenomenon has brought many people within the orbit of public health services for the first time and diseases previously not noticed have now made themselves apparent. It has also increased demands on already overburdened public health services. From their bridgeheads in the slums, the parasites may spread to other urban areas, reaching new hosts through vectors, through fecal contamination of soil, food, and water, and through transfused blood.

Transfusion-acquired malaria (especially *Plasmodium vivax* malaria) and Chagas disease pose particular problems as they are both easily transmitted by blood transfusion. Other parasites, such as the African trypanosomes (particularly *Trypanosoma gambiense*), *Babesia microti*, and the filarial worms such as *Brugia malayi*, *Loa loa*, *Wuchereria bancrofti*, *Mansonella ozzardi*, and *M. perstans*, may also be transmitted by blood transfusion but fortunately this mode of transmission is rare even in the endemic countries. It is not surprising that malaria has resulted from blood transfusion as plasmodia can remain viable in refrigerated blood for up to 10 days. In developing countries, transfusion malaria is most common in people who have received blood sold by low-income donors whereas in developed countries, transfusion malaria results from the migration of carriers

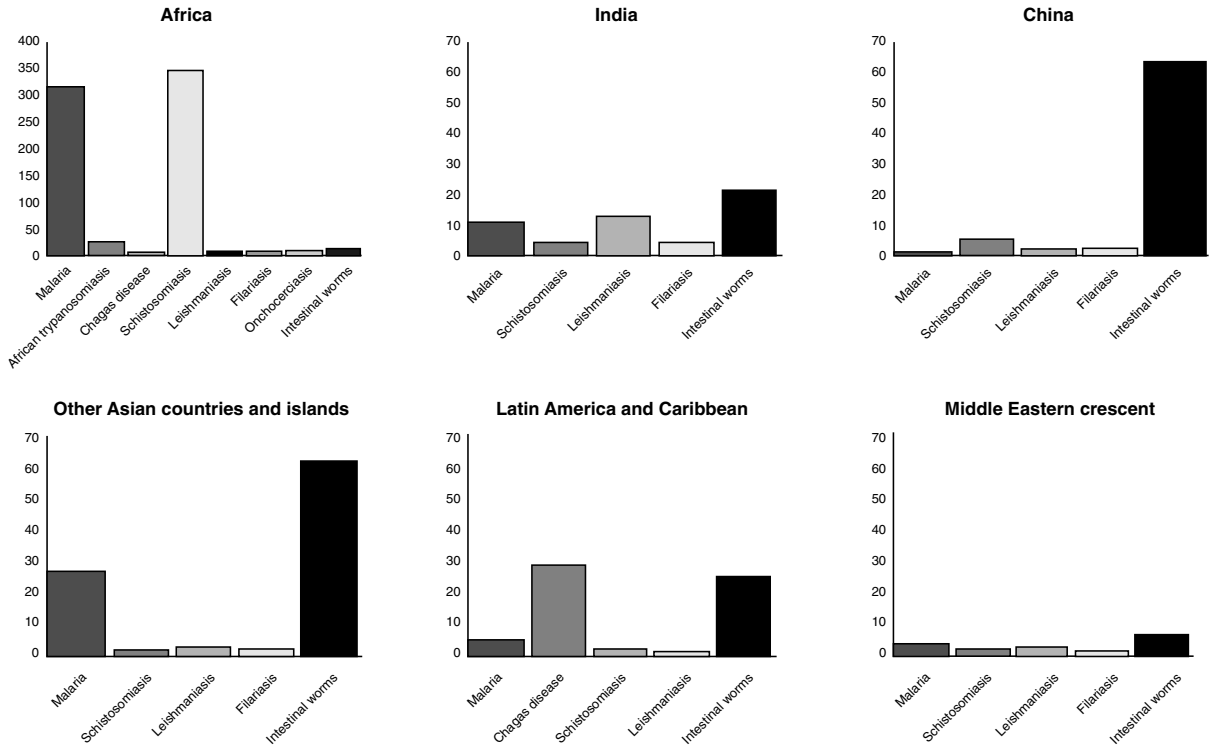

Figure 4 *Burden of disease caused by various parasitic diseases by regions, 1990 (hundreds of thousands of DALYs lost) (data from World Bank 1993b).*

from endemic areas. To avoid such infections, blood donation is not permitted in some countries from those who have had malaria or who have visited or lived in malarious areas. Individuals with positive serology for *T. cruzi*, the causative agent of Chagas disease, have been found among the 7 million or more legal immigrants from South and Central America to the USA. Their presence poses a risk of transmission of Chagas disease by blood transfusion. A similar risk exists in Europe where more than 250 000 immigrants from Central and South America now live (Schmunis 1994). Transfusion-transmitted *T. cruzi* infection has been reported in

Canada, the USA, and Spain (Villalba et al. 1992; Schmunis 1991). Infection may occur in nonendemic areas by means other than transfusion; for example, infection in a migrant was the cause of a case of congenital *T. cruzi* infection in Sweden.

As air travel has become more common, imported malaria has been seen with increasing frequency in Canada, the Caribbean, Europe, Oceania, and the USA and it has been stated that patients with malaria are now more often seen in temperate London (England) than in tropical Jamaica (West Indies) (Alleyne 1983). In the UK, 8 353 cases of imported malaria were diagnosed between 1987 and 1992 (WHO 1999) and more than 1 000 cases of imported malaria are detected yearly in the USA. For travelers in most areas of Asia, the species of *Plasmodium* responsible for malaria is usually *P. vivax*, whereas for travelers in Africa and some parts of Asia it is *P. falciparum*, and either or both species may occur in travelers in the Americas. There is a constant risk that travelers infected with plasmodia who return to areas where there are *Anopheles* mosquitoes susceptible to infection may start local transmission (Maldonado et al. 1986; Phillips-Howard 1991; López-Antuñano and Schmunis 1993). Malaria has also been reported in individuals living in nonmalarious areas who have never left that area and have never had a blood transfusion. Most cases have been acquired by people living near or passing through airports and have probably originated in airplane-transported infected mosquitoes.

Food-borne trematodes, such as *Opisthorchis* spp., are responsible for diseases in migrants from South East Asia and the eastern Pacific, and a high prevalence has been reported in refugees in camps in Cambodia and Laos and in Thai immigrant workers in Kuwait and China. Pulmonary paragonimiasis has been diagnosed in refugees from South East Asia residing in France and in the USA. Liver flukes have been found in immigrants from Asia to Europe and the USA (WHO 1995b). Ethiopian refugees in Israel also harbor liver flukes. The round worm *Strongyloides stercoralis* and the protozoa *Giardia duodenalis* and *Entamoeba histolytica* are among the parasites often acquired by migrants and by travelers to developing countries.

NON-HELMINTH PARASITES

African trypanosomiasis (sleeping sickness)

Trypanosomiasis, caused by *T. brucei gambiense* and *T. brucei rhodesiense*, is endemic in rural areas of 36 countries of sub-Saharan Africa, particularly in West, Central, and East Africa in areas where the tsetse fly is present. Sleeping sickness caused by the trypanosomes has eliminated entire communities in Africa. Outbreaks of sleeping sickness produced by *T. b. gambiense* continue to occur in Angola, Congo, Sudan, Uganda, and Zaire and *T. b. rhodesiense* is a serious threat in Tanzania and Mozambique. Sporadic cases of sleeping sickness have also been reported from some southern African countries (WHO 1986, 1994a). Even tourists to

certain areas of Africa can be affected, as shown by recent cases in UK travelers returning from East Africa (Moore et al. 2002). It is estimated that over 55 million people in 36 countries are at risk of acquiring sleeping sickness and that 250 000–300 000 people are infected. The yearly incidence is difficult to ascertain because surveillance is poor in the c. 200 confirmed foci of endemic sleeping sickness. The number of cases reported annually varies from 20 000 to 25 000 (WHO 1986, 1994a), and the estimated annual mortality 20 000 to 70 000 from 1990 to 2001. (World Bank, 1993b; WHO 1995a, 1996, 2000a, 2002).

The impact of the animal trypanosome disease, nagana, is also great, depriving much of Africa of milk, meat, and draught oxen for plowing and transport. The cost of these problems is more than US$4.5 million per year (Kabayo 2002).

Projects for economic development, if planned without proper consideration for their effects on the environment and on health, can cause unexpected health problems. Development projects for producing electricity and improving agriculture may change the local ecology and facilitate the spread of trypanosomiasis and other parasitic infections. For instance, they may encourage people to migrate to areas where their contact with parasites and their vectors is increased. Dams may displace villages, forcing people into tsetse-infested grasslands. Extensive lake margins may encourage growth of vegetation in which tsetse flies can breed, increasing the risk of bites among people who come to collect water. Such exposures may cause recrudescence of infection and even bring about full-blown epidemics (WHO 1986). Political upheavals and droughts may also stimulate life-style changes, many of which facilitate the spread of diseases. One of the most common consequences of civil disorder and of drought is the mass movement of people. While in transit, they are vulnerable to disease and many may become infected if they migrate into or across trypanosomiasis endemic areas.

If untreated, both forms of African trypanosomiasis are fatal, but there are important differences between the two forms of the disease. *T. b. gambiense* infections may run a protracted course of several years and infected individuals may serve as sources of infection if they migrate to areas where susceptible hosts and vectors are present. The disease caused by *T .b. rhodesiense* in East Africa causes death in weeks or (at most) a few months and, therefore, carriers pose less of a threat to individuals in uninfected areas. Melarsoprol has been used for the treatment of African trypanosomiasis for decades and eflornithine, which is much more expensive but has fewer side-effects and improves the overall cure rate, has been introduced for treatment more recently. An economic study in Uganda indicated that melarsoprol treatment is associated with an incremental cost per life and DALY saved of US$209 and US$8, respectively. Each additional life saved by switching from melarsoprol alone to a combination of melarsoprol and eflornithine would cost an extra US$1 033 per life saved, and an extra US$40.9 per DALY gained. Shifting from this second alternative to treatment of all patients with eflornithine would lead to an incremental cost per life saved of US$4 444 and an incremental cost of US$166.8 per DALY gained (Politi et al. 1995).

Programs for control of sleeping sickness are based on a combination of active and passive medical surveillance and on vector control. Costs include those incurred as a result of death and loss of productivity due to illness and those incurred as a result of the cost of treatment and disease control. The estimated cost from loss of income due to premature death from sleeping sickness is US$615–761 per person, varying in different areas and among different segments of society; the cost per individual is higher for those with a higher income. In 1984–85, the cost of surveillance was estimated at US$0.79–1.39 per person depending on the strategy used. The cost of treatment, including hospitalization, was US$35, US$88 and US$133 per person for treatment with pentamidine, suramin, and melarsoprol, respectively. Costs for prevention using screens and traps varied from US$2.30 to 11.50 per person. Ground-spraying costs were estimated at US$200–1000 per km. The cost per person protected by screens and traps depended on the number of people served per screen or trap and on the density of the population in the area under surveillance (WHO 1986).

American trypanosomiasis (Chagas disease)

Chagas disease occurs frequently in South and Central America, from Mexico in the north to Argentina and Chile in the south. Most of the people infected with *T. cruzi* in the Americas live in poor rural or semi-urban areas. Infected individuals have been detected in all Central and South American countries, including a few in French Guiana, Guyana, and Surinam. The only Spanish-speaking countries in the western Hemisphere where human *T. cruzi* infections have not been found are Cuba and the Dominican Republic. American trypanosomiasis also occurs as a zoonotic disease in the USA, where its range extends to Northern California in the west and to Maryland in the east.

Chagas disease is a major public health problem in Latin America. About 16–18 million people were considered to be infected and 90 million others exposed to the risk of infection in the 1980s. More recent data suggest that there are 11 million infected individuals (Table 2.5) and that 2–3 million have the cardiac and/or hollow visceral lesions that characterize the chronic stage of the disease. Many infected individuals show few or no clinical symptoms of disease and thus may not seek treatment. Infected individuals who are not treated

a) Total population the year the study was made or average population for the years the study was made (Schmunis 1994). Incidence data from 1990 and 1997 (Hayes and Schofield 1990; Schofield and Dujardin 1997);

b) Incidence data from these countries are not included because the beneficial effect of control programs is not considered in the calculation (Hayes and Schofield 1990).

... No data.

early after infection or in the early chronic stage of the infection will remain infected throughout their lives. The majority of cases of human infection occur in rural areas, particularly where houses are colonized by the triatome bugs that transmit the infection. The extent of vector transmission in the human population is related to socioeconomic status; poor people living in inadequate housing being most commonly infected. The infection persists wherever living conditions permit intimate contact between the triatome bugs and the human host. Prevalence in the general population is 0.34 percent in Ecuador, 1.25 percent in Uruguay, 11.5 percent in Paraguay, and 22.2 percent in Bolivia. Incidence estimates range from 3 320–4 030 for Costa Rica to 22 960–179 703 for Venezuela (Table 2.5) (Hayes and Schofield 1990; Schmunis 1994; Schofield and Dujardin 1997).

Transfusion is the second most common mode of acquiring the infection. Infection rates in blood donors vary from 6 to 12 percent in some areas of Argentina, Brazil and Chile and from 2 percent in Honduras to 48 percent in Bolivia. In 1997, six countries had more than 99 percent screening coverage for *T. cruzi*, but seven countries still showed risk of transfusion-transmitted infection that year (Schmunis et al. 2001). The risk of receiving an infected blood unit and acquiring a transfusion-transmitted infection has been reduced with time due to improvements in screening coverage (Schmunis 1999)

Congenital transmission, the third most common route of acquiring the infection, occurs in at least 3–5 percent of babies born to infected mothers (Schmunis 1994).

Chagas disease is a debilitating and incapacitating chronic condition that develops in 20 percent of those infected with *T. cruzi*, killing from 23 000 (World Bank 1993b) to 45 000 (Moncayo 1993) people every year in the early 1990s. Recent estimates suggest that mortality has decreased to 13 000 per year (WHO 2002). Chagasic cardiopathy was ranked third as a cause of disability in a rural area of Brazil where *T. cruzi* infection is endemic (Dias et al. 1985) and was also the main cause of early retirement in the region (Lopes and Chapadeiro 1986). In another endemic area of Brazil, 4–9 percent of all incapacity benefits received by individuals 30–50 years old were attributed to the effects of Chagas disease (Zicker and Zicker 1985). The number of productive years lost because of the disease among individuals 15–64 years of age in endemic areas of Brazil was estimated to be 2.275 and 1.369 per 100 000 population for males and females, respectively (Pereira 1984). Using data from the World Bank (1993b) study and from other sources, it is possible to compare the burden and general costs of Chagas disease with those of other diseases (World Bank 1993b). The disease burdens produced in 1990 by malaria (35 700 000 DALYs) and schistosomiasis (4 500 000 DALYs) world-wide are higher than that produced by Chagas disease (2 740 000 DALYs), but the Chagas disease burden is higher than those produced by leishmaniasis, African trypanosomiasis, leprosy, filariasis, and onchocerciasis (Figure 4). In Latin America, the burden of Chagas disease exceeds that of the so-called tropical diseases (i.e. malaria, schistosomiasis, and leishmaniasis) and intestinal worms. In Latin America, tropical diseases together produced a disease burden that was only about one-quarter of that caused by Chagas disease. The disease burden caused by Chagas disease is, moreover, the fourth highest among all infectious diseases that occur in the region. Only acute respiratory infections, diarrhea, and AIDS produced higher disease burdens. The situation has improved since 1990, and the burden of Chagas disease is now considered to be 676 000 DALYs (WHO 2002).

As the affected population is mostly at a low socioeconomic level, the cost of treatment is usually provided by the State. In Brazil in 1987, the estimated cost for pacemakers and surgery to correct enlarged viscera was US$250 million and the cost of lost labor by the 75 000 chagasic workers represented a loss of another US$625 million (Dias 1987). These costs did not include consultation, care, and supportive treatment, costs for which amounted to another US$1 000 per patient per year (Schofield and Dias 1991), or disability payments which, in one Brazilian State in 1987, were US$400 000 (Dias 1987). In Argentina, treatment of an acute case cost US$591.80; treatment of an asymptomatic case cost US$ 174.49; and treatment of one with cardiac lesions cost US$603.62 (del Rey et al. 1995). In the same country, the cost for 30 months of treatment of 128 patients who had cardiac lesions was US$350 000 (Evequoz 1993). If all patients from Bolivia who needed treatment were treated, that country would spend US$215 000 each year for treatment of patients with acute Chagas disease; US$21 million for treatment of chronic disease and US$186 000 for treatment of congenital disease. In 1994, direct costs to Bolivia as a result of deaths from the disease were US$343 000 per year and annual indirect costs of morbidity and mortality were estimated at US$43.8 and 57.5 million, respectively (Human Development Ministry 1994). In Chile, the yearly cost of the disease was estimated at US$37 million in addition to the cost of pacemakers and surgery for implantation of pacemakers (Apt 1991).

In addition to the costs of treatment, there are also costs associated with the control of vectors responsible for Chagas disease. The annual cost for vector control through insecticide spraying, housing improvement, and health education in countries infested with the vector *T. infestans* is large: US$100 000 for Uruguay; US$300 000 for Chile; US$18 million for Argentina, and US$25 million for Brazil.

Brazil spent US$516 682 000 in prevention and control activities, mostly for vector control, from 1975 to 1995. In 1978, it was estimated that there were 3 573 000 individuals infected with *T. cruzi*, 3.1 percent of the

population; by 1995 the seropositivity rate had decreased to 1.3 percent, 1 961 000 infected individuals. Between 1975 and 1995, vector control prevented 277 000 new infections and 88 000 deaths while the expenditures prevented (expected benefits) were US$847 million. The loss of 1 620 000 DALYs, 41 percent from averted deaths and 59 percent from averted disability (Akhavan 2000), was also prevented. These data indicate the benefit of vector control. Sustained vector-control activities were responsible for the interruption of *T. cruzi* vectoral transmission in Uruguay in 1997, Chile in 1999, and in nine of the 11 endemic states of Brazil in 2000–02.

Leishmaniasis

Leishmaniasis is considered to be endemic in Africa, in most countries of the Americas and Asia, and in many countries of Europe. Most cases of cutaneous leishmaniasis (more than 90 percent) occur in Afghanistan, Brazil, Iran, Peru, Saudi Arabia, and Syria. More than 90 percent of visceral leishmaniasis cases occur in Bangladesh, India, Nepal, and Sudan (WHO 1994b). In all its forms, there are 12–13 million cases of leishmaniasis worldwide; the annual incidence is 600 000 new clinical cases, and 350 million people are at risk of infection. The development of new territories, explosive migration, rapid urbanization and the associated environmental changes, are expanding the areas where human cutaneous leishmaniasis commonly occurs. Leishmaniasis is transmitted by sandflies and the clinical manifestations of infection vary depending on the species of *Leishmania* involved (WHO 1990a).

Cutaneous leishmaniasis is characterized by skin ulcers that heal slowly and leave scars. The species causing cutaneous leishmaniasis in the Old World are *L. tropica*, *L. major*, and *L. aethiopica*; the latter is also the etiological agent of diffuse leishmaniasis. In the New World, cutaneous leishmaniasis is mainly caused by *L. braziliensis*, *L. mexicana*, *L. amazonensis*, *L. venezuelensis*, *L. panamensis*, and *L. guyanensis*. *L. braziliensis* and *L. panamensis* are mainly responsible for mucocutaneous leishmaniasis, a condition in which cutaneous lesions spread to the mucosa of the mouth and nose and *L. mexicana* and related forms are responsible for diffuse cutaneous leishmaniasis in the New World (WHO 1990a; Rey 1991).

Cutaneous leishmaniasis is not usually life threatening, but clinical visceral leishmaniasis (kala azar) is often fatal if untreated. Visceral leishmaniasis is caused by *L. donovani* and *L. infantum* in the Old World and *L. infantum chagasi* in the New World. Although most infections are asymptomatic or subclinical, those associated with malnourishment often result in severe disease. In the Indian subcontinent, 400 000 new cases are estimated to have occurred each year with a case fatality rate of 5–7 percent. Large epidemics of kala azar occurred in India in 1978, 1982, and 1987 (WHO 1990a). An epidemic in Southern Sudan was first recognized in mid 1988 and, by 1993, 300 000–400 000 people were at risk of infection and 40 000 were thought to have died. In some villages, the population decreased by 30–40 percent as a consequence of the epidemic (WHO 1993a). Overall it is estimated that visceral leishmaniasis kills at least 50 000 people per year.

Prevention of cutaneous leishmaniasis is based on:

- case detection and treatment
- the destruction of sandflies and their breeding places
- the prevention of contact between humans and sandflies.

In addition to these measures, the canine reservoir must also be eliminated to prevent visceral leishmaniasis in the Mediterranean and American regions. Treatment costs (drug only) for cutaneous and mucocutaneous leishmaniasis vary from US$60 to 70 per person, in different regions. Control costs for visceral leishmaniasis are US$100 per person. When other related costs are included, the cost of each case of visceral leishmaniasis amounts to US$250. When treatment with amphotericin is needed (because of failure of other drugs to bring about cure) the cost of each case increases by US$45 (WHO 1990a, 1993a).

An epidemic of visceral leishmaniasis in Sudan provided an opportunity to obtain accurate data on excess mortality, the costs of intervention measures and their effects, thus making it possible to express the cost-effectiveness of intervention as the cost per DALY averted. The cost-effectiveness ratio of US$18.40 per DALY places the treatment of visceral leishmaniasis in Sudan among health interventions considered ‘very good value for money’ (i.e. interventions of less than US$25 per DALY) (Griekspoor et al. 1999).

Malaria

Malaria is the most important protozoal disease affecting humans. People suffering from malaria mostly live in poverty in rural areas where *Anopheles* mosquitoes are present. Over 40 percent of the world’s population remains exposed to varying degrees of risk from malaria and one or more types of malaria occur in 90 regions of the world (WHO 1994c, d, e). The global incidence of malaria is c. 120 million clinical cases each year, the parasite being carried by 300–400 million people. Countries in tropical Africa account for more than 80 percent of all clinical cases and more than 90 percent of all carriers (WHO 1992a, 1995a). The reporting of incidence figures for large regions tends to mask trends within countries and among countries in a region. The malaria situation has improved in some countries but has deteriorated in others. In India, the reduction in reported malaria cases from 9 million to 5 million between 1976 and 1984 was largely due to a

return to levels that had occurred before a peak just prior to 1976.

Some areas are particularly susceptible to epidemics of malaria. These include the 'frontier areas' in South East Asia and South America that have experienced substantial population increases and are now being rapidly developed. In the highly endemic areas of Africa, there has been little change in levels of infection, but epidemics associated with weather and population movement have occurred in areas of low endemicity (WHO 1992a). Worldwide distribution of malaria and major problem areas are shown in Figure 5 (WHO 1993b). Of the 5.3 million cases reported to the World Health Organization in 1992 (excluding the African Region), 75 percent were concentrated in six countries: Afghanistan, Brazil, Colombia, India, Sri Lanka, and Vietnam (WHO 1994c). Within these countries, malaria is concentrated in certain areas (WHO 1992a). In 1994, 27 million cases were reported from Africa, 1.1 million from the Americas, 3.5 million from South East Asia, 2.1 million from the western Pacific, 321 000 from the eastern Mediterranean Region, and 91 000 from Europe (WHO 1997a).

Severe and fatal malaria infections are usually caused by *P. falciparum*, the predominant species of malaria in tropical Africa *P. falciparum* is less common in the rest of the world. For certain areas, including 'frontier areas' and areas with civil war or other conflicts, illegal trade and mass movements of refugees, malaria mortality is probably greatly underestimated (WHO 1994c). For example, 1 428 deaths from malaria were reported from the Americas in 1986 but the annual malaria mortality for the Brazilian Amazon region alone (a 'frontier area') was between 6 000 and 10 000. Implementation of early diagnosis and prompt treatment through strengthening the local health services, has drastically decreased mortality by falciparum malaria in the Amazon Region of South America.

The vast majority of deaths from malaria occur in Africa, where the death toll so caused is now estimated to be at least 1 million per year in children (WHO 1993b). Between 1970 and 1975, malaria was responsible for 20–30 percent of infant mortality in Kenya and Nigeria and, in the Gambia, mortality from malaria was 6.3 per 1 000 per year in infants and 10.7 per 1 000 per year in children under 4 years of age (WHO 1992a).

Resistance of *P. falciparum* to the antimalarial drug chloroquine was detected almost simultaneously in Brazil, Colombia, Venezuela, and Thailand in the late 1950s and the 1960s. Several countries have now reported the widespread presence of *P. falciparum* strains resistant not only to chloroquine but also to amodiaquine, pyrimethamine in combination with long-acting sulfonamides, and to other drugs. The degree of resistance varies from country to country (López-Antuñano and Schmunis 1993). Resistance to *P. vivax* to chloroquine has been shown in Indonesia, Papua New Guinea, Myanmar, and Vanuatu (WHO 1997a).

P. falciparum has a high prevalence in areas that border jungles where the population is very mobile owing to expansion of agricultural and mining activities. In South America, these areas also have a high frequency of infection with *P. falciparum* strains resistant to antimalarial drugs. In such areas, migration favors contact between carriers and others who are susceptible to the infection. Exposure of large numbers of susceptible people to infected vectors gives rise to epidemics with high rates of morbidity and mortality. In these areas, the breakdown of the social structure, the absence of health service facilities, and the resultant failure of diagnosis and treatment of infected people adds to the risk of infection and death from malaria.

In many of the nations that are promoting national development and experiencing expanding populations, new roads are opened into jungle areas that are undergoing agricultural development and from which natural resources are being extracted. One of the detrimental consequences of such development is an increase in the incidence of malaria, mainly because of internal migrations. The destinations of the migrants are often determined by roads planned by development officers in remote cities without any thought for public health considerations. The migrants use the new roads to penetrate into jungle areas where disease vectors abound; here they often construct temporary dwellings that lack even minimum sanitary facilities. These areas often lack basic health and education programs as well as political and administrative organization, leaving the impoverished migrants vulnerable to disease. Some types of development program are particularly likely to increase the risk of malaria; for example, flood-based irrigation systems used for growing rice and banana crops. Poorly built roads, dams, and irrigation canals can also produce anopheline breeding sites, particularly during long periods of rain.

For most countries, the cost of malaria has been enormous. In the USA, it was estimated to be US$500 million in 1938 (Williams 1938). In Greece prior to the 1940s, the annual costs of malaria were huge: US$12 million for the loss of working days and earnings (using the minimum wage for the calculations), US$3.5 million for treatment and US$7.5 million for deaths (Livadas and Athanassatos 1963). In India, annual costs were US$50 million, US$60 million, and US$340 million, respectively (Sinton 1938). In the 1950s, lost wages amounted to US$60 million per year in Indonesia and US$14 million per year in the Philippines, where treatment costs were US$25 million per year and costs due to deaths were US$15 million per year (Wernsdorfer and Wernsdorfer 1988). The cost of deaths associated with malaria was estimated at US$157 million in Mexico for the period 1949–1963 (Wernsdorfer and Wernsdorfer 1988). In Paraguay, the economic potential

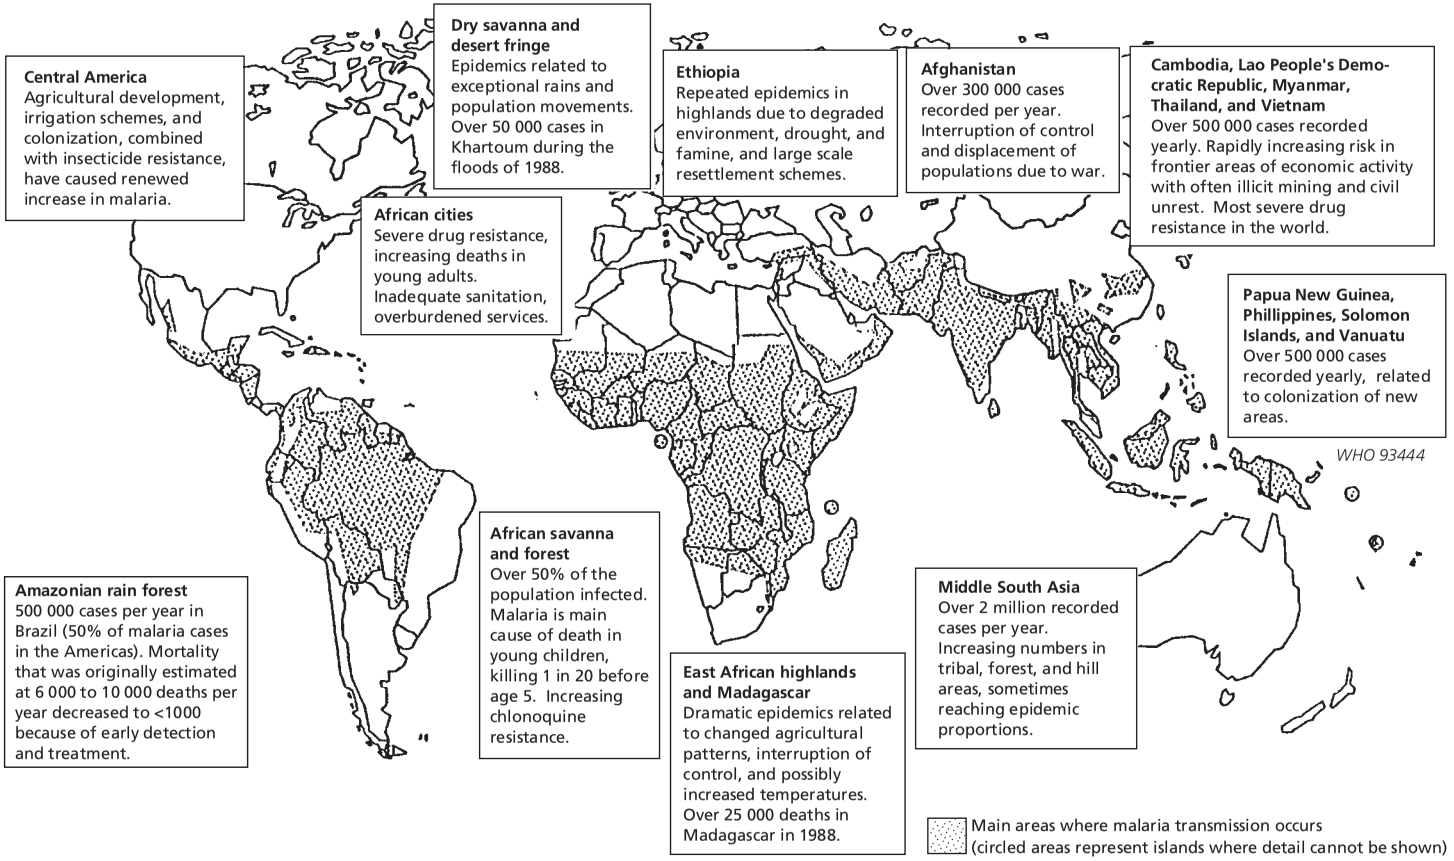

Figure 5 *Malaria distribution and problem areas (reproduced with permission from WHO 1993b).*

of a family with malaria was 74–86 percent of the potential of families without the disease (Conly 1975). In Peru in 1998, there were 77 000 cases of malaria with 43 deaths and the cost to the Peruvian economy was US$37.9 million that year, 1.5 percent of the total health expenditure. The government cost was US$ 9.3 million, 1 percent of the public health expenditure, The costs to families, who are mostly poor, amounted to US$26.6 million, averaging US$475 per family. The cost to families per malaria case was US$95, each family having an average of five cases (Ministry of Health 2000).

High malaria prevalence with its concomitant high social and economic costs interferes with the productivity and stability of agricultural settlements (Sawyer 1993). In Africa, the estimated average time lost by adults due to one episode of malaria were 6.2 days, 4.3 days, and 4 days in Sudan, Sri Lanka, and Burkina Faso respectively; in Kenya, Malawi, Nigeria, and Rwanda, on the other hand, it was 2–3 days (WHO 1999). In 1985 in Africa, a malaria episode in a person cost US$1.80 directly and US$9.80 indirectly. Another study showed that the cost of providing treatment was US$0.21 per child and US$0.63 per adult. The direct expenditures incurred as a result of malaria by low-income and high-income households during a year in Malawi were US$19.13 and 19.84, respectively and the indirect costs were US$2.13 and 20.61, respectively (Ettling et al. 1994). In the sub-Saharan countries only, the direct cost of malaria is estimated to be US$500 million annually (WHO 1999). Thus, it is not surprising that direct and indirect costs of malaria in Africa as a whole were estimated as US$800 million in 1987 (WHO 1993b) and were predicted to reach US$1.8 billion by 1995 (WHO 1995a).

The high costs caused by malaria are not limited to Africa. In Thailand in 1952, at the beginning of the intensification of the antimalarial program, the loss in agricultural production caused by malaria was US$1.52–1.90 million. Fourteen years later, this figure had decreased to US$0.30–0.37 million per year (Kühner 1971). The cost of the malaria control program was US$17 million in 1980 (Kaewsonthi and Harding 1984). Resistance to DDT and other insecticides and to chloroquine and other drugs has significantly increased the costs associated with malaria prevention and control.

In areas where the population is relatively stable, malaria can often be controlled by vector source reduction and the protection of households from vectors by various methods including indoor spraying with residual insecticides and insecticide-impregnated bednets. For migrant populations, the best approach for prevention and control is promotion of self-protection; for example, using screened tents, insecticide-impregnated bednets, and insect repellents. The efficacy and relative cost-effectiveness of insecticide-treated bednets for the control of malaria in children under 5 years of age have recently been demonstrated by several large-scale trials (WHO 2000b). However, it has been suggested that long-term use of insecticide-treated bednets in areas of high transmission could lead to mortality rebound in later childhood. This would reduce the cost-effectiveness of the intervention and, in the extreme, could lead to negative overall effects (Coleman et al. 1999).

In all situations, early detection and treatment will decrease morbidity and prevent mortality. Selection of the appropriate control measures requires assessment of the risk factors present in the area. In most cases, it is necessary to use several control measures in an integrated fashion (López-Antuñano and Schmunis 1993).

Among infants, severe anemia and malaria are often associated. The cost and effectiveness of control measures to prevent both anemia and malaria have been evaluated based on data from the expanded program on immunization (EPI) and not on the malaria control program. For severe anemia, and from the perspective of the health provider, the cost-effectiveness ratios were, respectively, US$8, 9, and 21 per DALY for malaria chemoprophylaxis with Deltaprim (a combination of 3.125 mg pyrimethamine and 25 mg dapsone) + iron, Deltaprim alone, or iron supplementation alone. For malaria prevention, Deltaprim + iron cost US$9.7 per DALY and Deltaprim alone cost US$10.2 per DALY. The cost-effectiveness ratios ranged from US$9 to 26 for severe anemia prevention and from US$11 to 12 for the prevention of clinical malaria. These measures were highly cost-effective, as defined by the World Bank's proposed threshold of less than US$25 per DALY for comparative assessments. Furthermore, all the preventive interventions were less costly than current malaria and anemia control strategies that rely on clinical case management. This economic analysis supports the inclusion of both malaria chemoprophylaxis and iron supplementation delivered through the EPI as part of the control strategies for these major killers of infants in parts of sub-Saharan Africa (Alonzo Gonzalez et al. 2000).

The success of malaria control programs has been uneven in some countries of the Americas. Such is the case in Brazil: malaria transmission was controlled elsewhere in the country by 1980 but not in the Amazon Basin where cases increased steadily until 1989 to almost half a million a year, and the coefficient of mortality quadrupled during the period 1977–1988. A reorganization of program activities from 1989 to 1996 facilitated a change towards earlier and more aggressive case treatment and more concentrated vector-control measures. The epidemic stopped expanding during 1990–1991 and reversed during 1992–1996. The total cost of the program from 1989 through mid-1996 was US$616 million: US$526 million for prevention and US$90 million for treatment. Compared to what would have happened in the absence of the program, nearly 2 million cases of

malaria and 231 000 deaths were prevented; the lives saved were almost equally due to preventing infection and to case treatment. Converting the savings in lives and morbidity into DALYs yields almost 9 million DALYs, 5.1 million from treatment and 3.9 million from prevention. Nearly all the gain came from controlling deaths and therefore from controlling *P. falciparum*. The overall cost-effectiveness was US$2 672 per life saved or US$69 per DALY, which is low compared to most previous estimates and compares favorably with many other disease-control interventions. Contrary to much previous experience, case treatment appears to be more cost-effective than vector control, particularly where *P. falciparum* is prevalent and unfocussed insecticide spraying is relatively ineffective. Halting the epidemic, by better targeted vector control and emphasizing treatment, paid off in much reduced mortality from malaria and in significantly lower costs per life saved (Akhavan et al. 1999).

In the Americas, good records of the cost of malaria control programs have been kept for several years and these indicate a continuous increase in the funds spent on antimalarial activities. Unfortunately, funding from international organizations and bilateral agencies has steadily decreased (Figure 6) (López-Antuñano and Schmunis 1993; PAHO 1994, 1995). Table 2.6 shows the overall budget for the health sector, the budget devoted to public health and the budget for malaria control programs in countries of the Americas in 1993 (PAHO 1994). From 1996 to 1999, expenditures by the 21 American countries with active control programs were US$263 million from the national budget and US$23 million from external contributions or loans. In 2000, countries spent US$105 million on malaria; US$97 million from the national budget and US$8.2 million from external contributions or loans (Organizacion Panamericana de la Salud 2000). Despite high expenditures for malaria control, the problem of malaria in the Americas remains unsolved.

Intestinal protozoa

Intestinal protozoa are the etiological agents of several widespread parasitic diseases, the most common of which are caused by *Entamoeba histolytica* and *Giardia duodenalis* (also known as *G. lamblia*).

Amebiasis, caused by *E. histolytica*, is a cosmopolitan infection transmitted by the fecal–oral route. Its greatest impact is in Africa and Asia. In Africa, Egypt, Morocco and countries located between 10°N and 10°S are severely affected. Prevalence is high in Asia, particularly in Bangladesh, Myanmar, China, India, Iraq, the Republic of Korea, and Vietnam. The amebae in these countries are highly pathogenic. Amebiasis is also a problem in Mexico and other Latin-American countries. On the other hand, in Europe and the USA, amebic infection is often asymptomatic or benign in spite of prevalence rates as high as 2–5 percent (WHO 1981). In 1984, it was estimated that 500 million people worldwide were infected with *E. histolytica* and that 40–50 million individuals had clinical symptoms of amebiasis, including diarrhea, dysentery, and liver disease. Worldwide amebiasis causes 40 000–100 000 deaths per year (WHO 1981, 1987, 1993c) and in 1996 was responsible for 48 000 cases (incidence) and 70 000 deaths (WHO 1997b).

The highest prevalence of *G. duodenalis* occurs in the tropics and subtropics where sanitation is poor. Transmission may be direct by ingestion of feces or indirect through ingestion of contaminated water or food. Travelers to tropical Africa, Mexico, Russia, South East Asia, southern Asia, and western South America are at a high risk of acquiring giardiasis (Wolfe 1992). Giardiasis may infect 200 million people worldwide and may produce symptoms in 500 000 individuals every year (Walsh and Warren 1979; WHO 1987, 1993c, 1997b). In developing countries, *G. duodenalis* is one of the first pathogens to infect infants and peak prevalence rates of 15–20 percent occur in children under 10 years old (Hill 1993). In developed countries, outbreaks frequently occur in child-care settings (Thompson 1994) and in adults who drink contaminated water. From 1977 to 1988, giardiasis was the leading cause of outbreaks of water-borne disease in the USA, causing an estimated 4 600 hospital admissions annually (Lengerich et al. 1994). Homosexual males constitute a special risk group. *Giardia duodenalis* may cause acute or chronic diarrhea, steatorrhea, loose stools, malabsorption of fat (Benenson 1990), and growth retardation and malnutrition in children (Farthing et al. 1986). Its major impact is on children under 3 years old, the undernourished, and the immunocompromised. It is also a cause of morbidity in adults (Farthing 1993).

Prevention of amebiasis and giardiasis is based on the implementation of good personal hygiene, appropriate disposal of human waste, and adequate handling and treatment of water supplies. The combination of filtra-

... No data.

tion and chlorination usually eliminates these organism from water, but higher concentrations of chlorine and longer exposure times are needed than those required for the elimination of bacteria. Boiling is an effective method of purifying drinking water for personal use.

There are few estimates of the cost of amebiasis, but one calculation suggested that in Mexico in 1984, expenditure for the treatment of invasive amebiasis was 1.6 percent of the budget of the Health Ministry (WHO 1987). In the developing countries, the costs associated with giardiasis are difficult to estimate because there are no hard data on the number of cases of diarrhea induced by giardiasis. An estimate made on the basis of the number of admissions to hospitals for giardiasis in the USA suggests direct costs of US$3–5 million annually.

THE HELMINTH WORMS

Dracunculiasis (Guinea worm disease)

Dracunculiasis occurs in 16 sub-Saharan countries in Africa, as well as in India and Pakistan. It afflicts the ten African countries considered to be among the least developed countries of the world, where the gross domestic product ranges from US$450 to 550 per inhabitant per year. The number of cases reported in the 1980s worldwide was 5–10 million and this decreased to 3 million in 1992, to 229 773 in 1993, and to 164 973 in 1994. Niger, Nigeria, and Sudan accounted for two-thirds of all cases from Africa (WHO 1993c, 1995c). During 1998, there were almost 72 000 cases reported from Africa, the most affected countries being Ghana, Nigeria, and Sudan (WHO 1999).

Dracunculiasis causes disability as a result of the migration of the parasite through the host. This migration results in localized pain, mainly in the areas around the joints. When the worm emerges through the skin, the pain at the site is severe and is accompanied by general symptoms of fever, joint pain, nausea, and vomiting. There is a painful edema followed by a blister and then an ulcer at the site of penetration. Extraction of the worm may cause disability for 2–4 weeks.

The success of the eradication campaign now underway in many countries is based on the provision of potable drinking water through the construction of safe wells. In infected areas, prevention is implemented through health education programs that convey the message that drinking contaminated water is the origin of the disease, that individuals with open blisters and ulcers should not be permitted to come into contact with any source of drinking water, and that water must be treated (by boiling, chlorinating or filtering) to eliminate the larvae of the crustaceans that act as the intermediate hosts. In Nigeria, control of the intermediate host costs US$3.00 per household for water filters and US$1 per capita for cement ring wells. This amounts to c. 30 percent of the estimated potential losses suffered in a season due to incapacity caused by the disease (Guyatt and Evans 1992).

Filariasis

About 750 million people in 76 countries live in areas of endemic filariasis, an estimated 90 million of them are infected with filariae. Of these, 72.8 million are infected with *Wuchereria bancrofti* and 5.8 million are infected with a variety of species of *Brugia* (WHO 1993c). There are 300 000 individuals infected with filariae in seven countries of the Americas; 48.6 million in eight countries of South East Asia (4.8 million infected with *Brugia*); 3.9 million in 14 countries or territories of the western Pacific (1 million infected with *Brugia*); and 25.6 million in 40 countries in Africa (WHO 1992b). Almost 40 million people worldwide suffer from lymphedema, elephantiasis or hydrocoele caused by bancroftian filariasis, 14 million of them in Africa and 21 million in South East Asia. Worldwide, *Brugia* is believed to cause lymphedema and elephantiasis in 2.8 million people of whom 1 900 000 are in South East Asia and 900 000 are in the western Pacific (WHO 1994f).

Clinical manifestations of bancroftian and brugian filariasis vary widely in different geographical areas from asymptomatic microfilaremia and malaise to acute symptoms characterized by adenolymphagitis with fever, hydrocoele, lymphedema, elephantiasis, and chyluria, the last four being characteristic of chronic bancroftian filariasis (WHO 1992b). In India, it is estimated that an infected person suffers 4.47 acute attacks per year if they have bancroftian filariasis and 2.20 acute attacks per year if they have brugian filariasis. Each attack has an average duration of 4 days and the numbers of working days lost per year per person are 17.43 and 8.91, for bancroftian and brugian filariasis, respectively (WHO 1992b).

The vectors of filariasis are *Culex*, *Anopheles*, *Aedes*, and *Mansonia* mosquitoes. Slum dwellers with poor housing and sanitation are at the highest risk of bancroftian filariasis transmitted by *C. quinquefasciatus* whereas the rural poor suffer more from filariasis transmitted by other mosquitoes. Control measures are directed towards reduction of vector density and interruption of contact between human and vector by the application of a combination of chemical or biological control measures, environmental management, and personal protection measures (WHO 1992b). Treatment is another factor in control and involves annual administration of a single dose of diethylcarbamazine (DEC) or a combination of DEC and ivermectin (WHO 1994g). Ivermectin is the drug of choice for both individual treatment and mass-treatment programs for the control of onchocerciasis (Ottesen 1994) and a single dose can also be used for treatment or as a control measure for lymphatic filariasis (Brown et al. 2000). The combinations of DEC plus ivermectin or ivermectin plus

albendazole caused a decrease in microfilaremia greater than that achieved with either drug alone (Ismail et al. 1998; Beach et al. 1999). Thus, combinations of DEC or ivermectin with albendazole could be effective for mass treatment of lymphatic filariasis and at the same time would decrease the burden produced by soil-transmitted helminth infections. Control costs vary with the scope of coverage and the strategy or combination of strategies used. Control costs are US$1.8 million in China; US$1 million in India and Thailand; US$500 000 in Egypt and Malaysia; and from US$27 000 to 300 000 in French Polynesia, Papua New Guinea, and Sri Lanka (WHO 1994g).

Between 75 and 122.9 million people are at risk of onchocerciasis (river blindness), which is endemic in 28 countries in Africa and six countries in the Americas. In Africa, 17.7 million people are infected with *Onchocerca volvulus*, of whom 500 000 have damaged vision and 267 000 are blind. In the Americas, 140 000 people are infected with *Onchocerca* of whom 750 are blind (WHO 1995d). Many individuals infected with *O. volvulus* are asymptomatic. Symptoms of acute dermal or ocular infection are rare clinical manifestations of chronic established infection, the most severe consequences of which are reduction of the visual field and blindness. The impact of the disease is seen mainly in sub-Saharan countries where, in some areas, up to 40 percent of adults may have severe visual impairment. This results in an inability of the family to support itself and a decrease in agricultural output that leads to unstable communities (WHO 1995d).

Control activities were originally based on control of the vector of onchocerciasis, the blackfly *Simulium*, but are now based on yearly administration of single doses of ivermectin to those at risk. Evaluation of a community-directed, ivermectin-treatment program in Uganda indicated that desired treatment coverage of the population eligible to take the drug, was achieved in 42.6–51.0 percent of the communities. The annual cost per person treated with ivermectin was higher in the districts with small populations (fewer than 15 000) than in those with large populations (more than 40 000), US$0.40 as opposed to US$0.10 or less (Katabarwa et al. 1999). The costs of ivermectin distribution vary between US$0.10–5 per person per year (WHO 1995d). Implementation of control measures has been successful in many areas and has resulted in interruption of transmission in 11 countries of West Africa. Levels of infection in children have been significantly reduced and the numbers of infected people decreased from 1 million in 1975 to 10 000 in 1992. Since the inception of the prevention program, 100 000 people have avoided blindness.

Food-borne trematode infections

Food-borne trematode infections have their highest prevalence in South East Asia and in the western Pacific; they are also present in areas of Africa, the Americas, and Europe. The geographical areas involved are expanding as are the populations at risk as a result of improvements in transportation that favor population movements and trade. It is estimated that food-borne trematode infections affect 40 million people throughout the world (WHO 1995b). The food-borne parasites of greatest public health importance are *Fasciola*, *Clonorchis*, *Paragonimus*, and *Opisthorchis*.

Human fascioliasis, caused by *F. hepatica* and *F. gigantica*, has been reported from Bolivia, China, Ecuador, Egypt, Iran, Peru, Portugal, and Spain; and 2.4 million people are infected. Clonorchiasis has been observed in China, Hong Kong, Macao, Republic of Korea, Russia, and Vietnam and estimates suggest that 7 million people are infected. Opisthorchiasis, caused by *O. viverrini* and *O. felinus*, occurs in Kazakhstan, Laos, Russia, Thailand, and Ukraine; 10 million people are infected. Of less importance from the public health viewpoint are the intestinal flukes that cause echinostomiasis, fasciolopsiasis, heterophyiasis, metagonimiasis, and nanophyetiasis. These infections are found in China, Egypt, Japan, Republic of Korea, Russia, and Thailand and c. 1.2 million people are infected (WHO 1995b).

The epidemiology of these diseases is determined by ecological and environmental factors. Aquatic or semi-terrestrial snails are the intermediate hosts and the reservoir hosts are fish, crustaceans or mammals. Human infection occurs from ingestion of raw or uncooked fish, shellfish or aquatic plants that harbor the infective metacercariae (Figure 7). In some areas, industrial production of cultured fish and shellfish may be related to the spread of food-borne trematodes (Benenson 1990; WHO 1995b).

To prevent human *Fasciola* infection, infection of livestock must also be controlled, as humans are only accidental hosts. The consumption of watercress or other aquatic plants from areas where sheep or cattle graze should be avoided, as should be the use of animal feces for fertilizing water plants. Mollusk hosts should be eliminated when possible. The best method for prevention of infection with *Clonorchis* and *Opisthorchis* is to avoid eating raw fish and to use sanitary methods for disposal of feces. Infection with these parasites is serious as they not only produce liver disease but also increase the risk of cholangiocarcinoma. *P. westermani* and several other related species cause lung fluke disease. These parasites have freshwater crabs as their intermediate hosts and prevention is effected by thoroughly cooking crustacea, by disposal of sputum and feces in a sanitary manner and by snail control when feasible (Benenson 1990). In migrants to developed nations, lung fluke infection is often misdiagnosed as tuberculosis. Programs for control of food-borne trematodes should be multisectoral, integrating the activities related to human health, food safety, aquaculture, agriculture, and education (WHO 1995b).

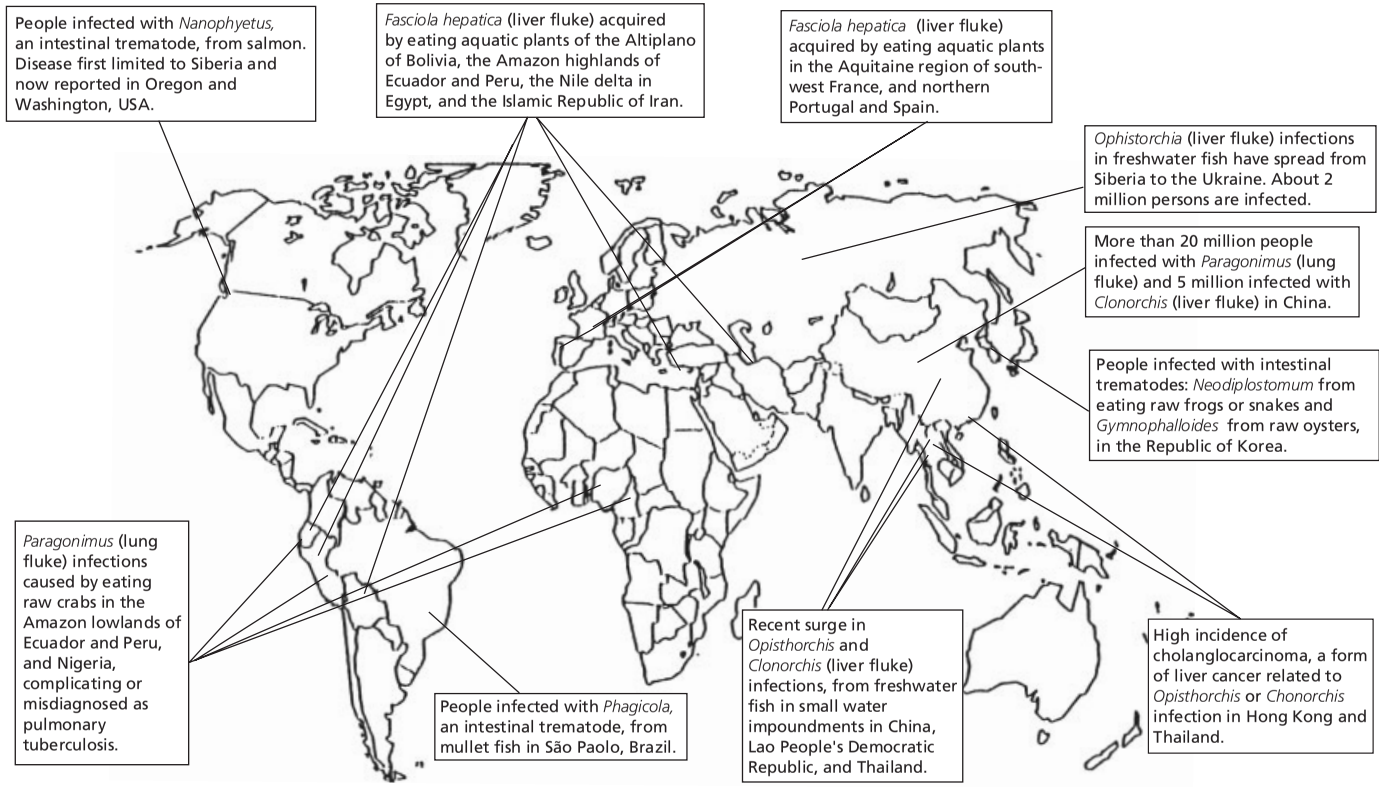

Figure 7 *Food-borne trematode infections: the global distribution is changing with the environment and with changes in human behavior (reproduced with permission from WHO 1995b).*

The economic burden of these diseases stems from a number of direct and indirect costs associated with the infections, including morbidity, loss of productivity, absenteeism, and cost of healthcare in infected people as well as losses in agricultural and aquacultural enterprises. The wages lost annually in Thailand as a result of opisthorchiasis in those aged 15–60 years are estimated at US$60 million and the cost of medical care is US$19.4 million. In addition, the cost of control for a 6-year period (1988–1993), with a coverage of 3 million people, was US$8.3 million, including costs for fecal examinations, drugs, and the promotion and training of personnel for community participation in control programs. In the Republic of Korea, control programs provide medical examinations and treatment for 15 million people and cost an estimated US$2.5 million per year (WHO 1995b).

Intestinal worms: *Ascaris*, hookworm, and *Trichuris*

Ascaris lumbricoides infections have been reported during the last few years from more than 150 of the 208 states and countries of the world. Hookworms and the whipworm, *Trichuris trichura*, are as widely distributed as *Ascaris* (Bundy and Cooper 1989; WHO 1987). These parasites are soil-transmitted helminths of global importance. Strongyloidosis has a patchy global distribution and is less prevalent than ascariasis. *Ascaris* has high prevalence in the subtropical and tropical areas of Africa, Asia, and the Latin-American countries. Although common in humid parts of the world, *Trichuris* is also found in temperate climates. Hookworm infection has almost been eradicated from Europe and the USA. The hookworm *Necator americanus* occurs in the Americas, equatorial Africa, southern Asia, South East Asia, Polynesia, and Australia. *Ancylostoma duodenale*, another hookworm, is more common in Africa and in northern and south-western Asia. The ranges of both species of hookworm (and of other parasites of global importance) often overlap.

During 1977–1978, 800–1 000 million people were infected with *Ascaris* and, of these, 1 million had symptoms; hookworm infected 700–900 million people, of whom 1.5 million had symptoms; and *Trichuris* affected 500 million people of whom 100 000 had symptoms. The number of deaths due annually to *Ascaris* and hookworms in this period were approximately 20 000 and 50 000, respectively (WHO 1993c). Subsequently, it was reported that *Ascaris* and *Trichuris* cause clinical symptoms in 214 and 133 million people, respectively, and that hookworm causes clinical symptoms in 96 million (WHO 1995a). More recent estimates for *Ascaris* are 1 400–1 500 million infected, 120–220 million cases (Albonico et al. 1999) and 4 000 deaths (WHO 2002). An estimated 1 049 million people harbor *Trichuris* (Crompton 1999); 114 million of them are preschool children and 233 million are children aged 5–14 years (Chan 1997). It is estimated that 27 million school-age children are infected in sub-Saharan Africa, 7 million in India, 42 million in China, 70 million in the rest of Asia, 39 million in Latin America and the Caribbean, and 18 million in the Middle-Eastern Crescent (Stephenson et al. 2000). Deaths attributed to *Trichuris* and hookworm were 2 000 and 4 000, respectively (WHO 2002).

The impact of these parasites on public health is related to the severity of the infection; heavy infections cause malabsorption and large blood and protein losses that are compounded in the context of poor nutritional status. Heavily infected people are also at risk of developing complications such as intestinal obstruction or anemia. The impact of these parasitic diseases is difficult to evaluate, as they may cause effects such as retarded physical growth, retarded development of cognitive skills, low participation in education, and poor performance (Evans and Jamison 1994). None of these effects is easy to isolate and measure routinely. Although there is a relationship between parasitic infections and human malnutrition, it is sometimes difficult to determine which is the primary factor because there are similarities in the socioeconomic conditions in which these conditions both occur (Crompton and Nesheim 1982).

Ascaris is mainly prevalent in young people (i.e. children aged 6–12 years). *Trichuris* infections peak in early life and then generally remain steady, whereas hookworm prevalence peaks in adolescence. Heavy worm burdens of *Ascaris* and *Trichuris* are found in children of primary school age (WHO 1981, 1987).

In many communities, 15 percent of the infected population harbor more than 60 percent of the worms. As morbidity is usually related to intensity of infection, heavily infected individuals have a greater risk of developing disease symptoms, and they also cause the most contamination of the environment (Anderson 1986). In addition, individuals with a heavy worm burden are more likely to re-acquire heavy infection after treatment and to suffer from polyparasitism (Anderson and Medley 1985; Bundy and Cooper 1989). The growth and nutrition of children are adversely affected by *Ascaris* and *Trichuris* infection and there are remarkable improvements in appetite, food intake, digestion, absorption, and growth in infected children who receive treatment (Cooper et al. 1990; Stephenson et al. 1989). Hookworm infection often causes iron-deficiency anemia, which may reduce productivity in affected individuals. The infection and the resulting anemia may impair mental development in children, negatively influencing their cognitive performance. Infection may also complicate pregnancy (Stephenson 1984; Prescott and Jancloes 1984; WHO 1987).

The cost of infection by intestinal worms is huge. In the late 1970s, US$4.4 million was annually lost in Kenya in the form of nutrients wasted as food unab-

sorbed by worm-infested people. In the same country in 1976, the cost incurred by the government for treatment of parasitic intestinal infections was US$339 000 (costs for examining patients and for drugs) and the cost incurred by affected families US$394 000 (cost for drugs, lost wages, and for transportation). These figures seem to be low as 88 804 patients were admitted to hospitals in Kenya that year as a result of ascariasis (Stephenson 1984; WHO 1987).

Programs for prevention of infection with intestinal worms must be based on the use of several strategies, focusing on improvements in basic sanitation, waste disposal, health education, and health services. In the short term, immediate action can be taken by administering the drug albendazole, which decreases morbidity and mortality. One strategy is to select the target population and then treat only those who are infected. This approach requires screening the entire population. It has been estimated that in Rwanda, application of this strategy would cost US$600 000 in salaries, excluding costs for the collection and handling of samples. Treatment of infected individuals (about two-thirds of the population for round worms and one-third for flat worms) would cost US$64 000 per year. An alternative program using chemotherapy (piperazine and niclosamide) on all individuals has been estimated to cost US$440 000 per year (De Schaepdryver 1984). Improving basic environmental sanitation and treatment facilities would be considerably more expensive than either of these policies. Control of these parasites requires a massive effort to raise the standard of living of the affected population if the benefits of any treatment programs are to have a lasting effect.

Schistosomiasis

Schistosomiasis is the most important and prevalent of the water-borne parasitic diseases. It is a major health risk in the rural areas of 74 developing countries. Five species of *Schistosoma* affect humans:

1. *S. mansoni* occurs in 36 countries in Africa, nine in the Americas, and seven in the eastern Mediterranean
2. *S. japonicum* is found in China, Indonesia, the Philippines, and Thailand
3. *S. mekongi* occurs in Cambodia and Laos
4. *S. intercalatum* is present in five countries in Central Africa
5. *S. haematobium* is prevalent in 51 eastern Mediterranean and African countries and in India and Turkey.

The first four of these species cause intestinal schistosomiasis and *S. haematobium* causes urinary schistosomiasis. It is estimated that more than 200 million people residing in rural and agricultural areas are infected with schistosomes and that 500–600 million people are exposed to infection. The estimated mortality was about 200 000 per year (WHO 1985, 1993d, 1994h) but has now decreased to c. 17 000 (WHO 2002).

The prevalence of schistosomiasis within countries varies widely: in some countries, the entire population is exposed; in others, there are only scattered foci of disease. Morbidity also varies widely, the foci of clinical disease usually being highly localized. The incidence of clinical schistosomiasis may be significantly higher in countries where the prevalence of the infection is greater than 40 percent (WHO 1985). In the past 10 years, the incidence and prevalence of schistosome infection have decreased in some areas but the infection has become more widespread in others. Large hydroelectric and agricultural irrigation projects (some involving the creation of artificial water reservoirs) and associated population movements are considered to be responsible for many of the increases.

Rates of infection with schistosomes are higher for men than for women because cultural and social biases in behavior and occupation cause men to be more exposed to contaminated water. Of the individuals infected with *S. haemotobium,* 60–70 percent are aged 5–14 years and this group is also the most heavily infected group in areas where *S. haemotobium* is endemic. Hematuria is present in 80 percent of infected children. The prevalence and intensity of urinary disease is lower in older age groups. In contrast, *Schistosoma japonicum* infection has no typical age prevalence and intensity distribution (WHO 1985, 1993d). In areas endemic for *S. mansoni*, the highest prevalence of infection is in those aged 10–24 years, but the prevalence in older groups may also be high. Usually, the most heavily infected individuals are those aged 10–14 years. A significant proportion of these individuals (those with an egg count of fewer than 800 eggs per gram of feces) have hepatomegaly and splenomegaly (WHO 1985, 1993d). Poverty, ignorance, substandard housing, and poor sanitation are the main factors that maintain these endemic foci.

Several studies have been made on the public-health impact of schistosomiasis. In these studies, the following parameters have been assessed: school performance, physical fitness, growth, productivity, and earnings. Although results have not been conclusive (Tanner 1989) there is consensus that in north-eastern Brazil, Egypt and Sudan there is a severe reduction of the work capacity of the rural population as a consequence of schistosomiasis (WHO 1994h).

The economic impact of schistosomiasis is partly a result of the large number of working days lost per infected person per year. This loss is 4.4 days and 40 days per year per person for those infected with *S. haematobium* and *S. japonicum*, respectively. About 10 percent of people infected with *S. mansoni* develop severe symptoms. The number of days of life lost because of schistosomiasis is c. 600–1 000 per case

(Walsh and Warren 1979). The global burden caused by schistosomiasis was 4 500 000 DALYs in 1990 (World Bank 1993b), but decreased to 1 760 000 DALYs in 2001 (WHO 2002).

The annual per capita cost for control of schistosomiasis depends on the nature of the program used. In Central Liberia, focal application of a molluscicide (niclosamide) was combined with mass chemotherapy. A three-dose metrifonate mass treatment was applied in one area with *S. haematobium* infections only, concurrent metrifonate and niridazole mass treatment in one dose was applied in another area with *S. haematobium* infections only, while in another area with both *S. haematobium* and *S. mansoni*, praziquantel (1 dose) was used. The costs per capita protected were US$3.33 for metrifonate, US$1.53 for metrifonate and niridazole combined, and US$1.67 for praziquantel. These figures do not include costs of parasitological examinations (Saladin et al. 1983). In the case of Saint Lucia, the costs were US$1.10 per person per year for chemotherapy, US$3.70 for snail control, and US$4.50 for a clean water supply (US Congress 1985). Costs per protected person were estimated at US$0.70–3.10 per year in three African countries. This amount may seem little, but it should be taken into account that total health expenditures per person in these countries varied from US$1 to US$3 per person per year (Gryseels 1989). Case detection of infected individuals in Sudan cost US$0.03 per capita per year, just for operating the health services. In Brazil, the costs, including laboratory diagnosis, consultation, and drugs, were US$3.73 (Guyatt and Evans 1992). The introduction of specialized programs, instead of using the general health services for control of schistosomiasis, increased the annual cost per person from US$1.50–6.53 (WHO 1993d). A schistosomiasis control program for control of *S. haematobium* or *S. mansoni* in a rural area with a population of 100 000 will have a 5-year cost of US$3.70–25.91 per capita. The variation is determined by the prevalence, intensity and rate of infection in the population (Rohde 1989).

Miscellaneous worms of regional importance

In addition to the parasites of global importance, there are others of regional or national relevance. These are the roundworms *Capillaria philippinensis*, *Enterobius vermicularis*, and *S. stercoralis*, the cestodes *Hymenolepis nana*, *Taenia saginata*, *T. solium*, and *Diphyllobothrium latum* and the trematode *Fasciolopsis buski* (WHO 1987). It has been estimated that there are 80–100 million cases of *Strongyloides*, 400 million of *Enterobius* and 78 million of *Taenia* worldwide (WHO 1990b; Warren et al. 1993). The most widespread of these worms is *S. stercoralis* which is prevalent in tropical and subtropical areas and is a severe problem in South America and the Caribbean. *Enterobius* is cosmopolitan, but human infections are most common in temperate regions and it is often found in developed countries in the northern hemisphere (WHO 1981, 1987). Morbidity is usually low. Taeniasis, caused by *T. saginata*, is also cosmopolitan but is most prevalent in African countries south of the Sahara, eastern Mediterranean countries, and in parts of the former Soviet Union. Lower prevalences are found in Europe, India and southern Asia, Japan, the Philippines, and much of Latin America. The lowest prevalences are found in Australia, Canada, and the USA (WHO 1979). *T. solium* is mainly restricted to poor socioeconomic areas of central and southern Africa, Mexico, Central and South America, and southern Asia. Sporadic cases are found in southern Europe (WHO 1979). Human cysticercosis, caused by the larval stages of *T. solium* in tissues, is far more important as a public health problem than is human taeniasis (i.e. the adult form in the intestine). The highest prevalences of human cysticercosis are found in some areas of Africa, Asia, and South America (WHO 1981, 1987). In Mexico, hospitalization and treatment costs for humans with neurocysticercosis was US$17 million annually (Murrell 1991).

EXPANDING THREATS

New diseases may emerge as a result of changes in ecology, human demographics, and human behavior. Factors such as international travel and commerce, introduction of new technology and industry, microbial adaptation and change, breakdown of public health measures, and social disorder all affect human health (Institute of Medicine 1992; Morse 1995). As a result, several parasites, such as *Anisakis*, *Babesia*, *Cryptosporidium*, *Cyclospora*, *Giardia*, microsporidians, *Plasmodium*, *S. stercolaris*, and *Toxoplasma gondii* may be poised for an increase in importance (Institute of Medicine 1992; Wurtz 1994). This list could also be extended to include a number of other parasites. Some of these parasites (i.e. *Giardia*, *Plasmodium*, *Strongyloides*, and *Schistosoma*) and the factors that favor their emergence or reemergence, have been mentioned before. For example, schistosomiasis has increased in incidence in many areas after the construction of dams. A brief review of the others follows.

Anisakis is a common parasite of marine mammals and fish and the etiological agent of herring worm disease (anisakiasis) in humans, who are incidental hosts. Humans are infected by larvae present in undercooked fish, squid or octopus. The larvae localize in the gastrointestinal tract and then migrate upwards, attaching to the oropharynx. Many cases have been observed in Japan, where it is customary to consume raw fish. Infected fish can be transported around the world and the incidence of infection is increasing because of the growing trend in the consumption of raw fish. Cases have been reported in the Americas, Asia,

Europe, and the South Pacific (WHO 1987; Benenson 1990; Institute of Medicine 1992). Prevention is effected by not eating raw fish.

Babesia microti, a protozoan transmitted by nymphs of the *Ixodes* tick, infects red blood cells, and is carried mainly by deer mice. Human babesiosis is usually a result of infection by *B. microti* but other species of *Babesia* have also been implicated. Babesiosis in humans has been observed in Mexico, Europe, and the USA. The emergence of cases in the USA is linked to reforestation and a resultant increase in the deer population and the number of deer mice. Preventive measures include the elimination of deer mice in the vicinity of human habitations and the use of tick repellents (Benenson 1990).

The coccidian *Cryptosporidium parvum* was recognized as a human pathogen less than 30 years ago. Cryptosporidia live intracellularly in the gut cells of humans and domestic animals such as cattle. Transmission is by the fecal–oral route with direct person-to-person and animal-to-person transmission and indirect water-borne transmission. The parasite is found worldwide and its importance as a human pathogen was recognized as a result of several small outbreaks that were either water-borne or food-borne and one massive outbreak associated with drinking water (the latter affected more than 400 000 people in Wisconsin, USA). In immunocompetent individuals, the infection may be asymptomatic or it may produce an acute or persistent diarrhea. Individuals immunosuppressed because of infection with human immunodeficiency virus (HIV) or from other causes have been the most severely affected, experiencing cryptosporidiosis as an aggressively opportunistic infection. Prevention should be achieved by improving surveillance of water purification plants to detect malfunction and by applying high standards of personal hygiene. Appropriate measures include the sanitary disposal of human feces and animal excreta. Chemical disinfection of water is ineffective against cryptosporidia because the oocysts (the infective stage) are very resistant to chlorine (Benenson 1990; Fraser 1994; Colley 1995).

Described in 1979, *Cyclospora cayetanensis*, another coccidia, is now recognized as producing long-lasting diarrhea in humans in North, Central and South America, and the Caribbean, as well as in South East Asia and Eastern Europe. It is transmitted through contaminated water or food, but is highly unlikely to be transmitted from person to person because oocysts require days or weeks to sporulate and become infectious (Ortega et al. 1993; Wurtz 1994). An outbreak of c. 850 cases occurred in Canada and USA (Centers for Disease Control 1996). *C. cayetanensis* may be the origin of persistent diarrhea in immunocompromised patients with AIDS. Prevention is similar to that of the other food- or water-borne diseases.

Microsporidia are normally parasites of animals other than humans. Four genera of microsporidia, *Encephalitozoon*, *Enterocytozoon*, *Nosema*, and *Trachipleistophora*, have been recognized as human pathogens worldwide, usually affecting the immunosuppressed, including those with HIV. *Encephalitozoon* has been reported to cause systemic infection with central nervous system and kidney involvement; *Nosema* is considered to be the cause of keratitis; and *Trachipleistophora* has been recognized as an agent of myositis. *Enterocytozoon*, which causes the majority of microsporidial infections in humans, produces chronic diarrhea in AIDS patients. The mode of transmission of microsporidia to humans is unknown (Desportes et al. 1985; Canning and wHollister 1987; Shadduck and Greeley 1989; Centers for Disease Control 1990; Orenstein et al. 1990; Cali et al. 1991; Madi et al. 1991; Molina et al. 1993; Pol et al. 1993).

Toxoplasma gondii is a coccidian parasite of cats that produces disease opportunistically in immunosuppressed humans on all continents. Infection is also common in immunocompetent individuals, but most of them are asymptomatic. Infection occurs as a result of eating infected raw or undercooked meat from the intermediate hosts (sheep, swine, chicken, goats, cattle or birds) or by ingestion of food or water contaminated with oocysts from cat feces. Transplacental infection occurs when pregnant women acquire the infection during pregnancy. Prevention is based on personal hygiene, avoiding eating raw or undercooked meat, and avoiding contact with cat feces. Patients with AIDS must receive prophylactic treatment to prevent disease caused by *Toxoplasma* (Benenson 1990; Wong and Remington 1994). Human toxoplasmosis in the USA is estimated to be an annual economic/public health burden of more than US$400 million. (Murrell 1991).

CONCLUSION

Infectious disease must be viewed as a global problem, a problem exacerbated by dynamic ecological changes brought about by technological, socioeconomic, environmental, and demographic changes, as well as by microbial change and adaptation (Institute of Medicine 1992). The mobility of modern humans and the evolution of parasites (including drug-resistant strains) mean that parasitic diseases are a threat in both developing and developed regions.

Parasitic infections cause human suffering and economic losses worldwide but the burden is greatest in underdeveloped countries. Millions of people are at risk of infection, disease, and death from protozoan and metazoan parasites. These parasites cause social problems and their effects are increased by the conditions in disordered societies. Their presence hampers educational, political, and economic development, imposing a tremendous burden on the already precarious health services in the poor areas of the world. This situation constitutes a serious public health concern and

inhibits the healthy development of individuals and social groups (Tables 2.4 and 2.7).

In developed countries, worms and protozoa present increased threats because of population movement, trade, and changing life-styles. Implementation of prevention and control strategies requires a systematic multidisciplinary and multisectoral approach.

For many diseases, there is sufficient knowledge to develop successful control programs. The following factors are vital:

- knowledge of the means of spread of the parasite and of any reservoirs
- a means of detecting both clinically apparent and asymptomatic infection
- a system of treatment or a method of interrupting spread.

In addition, the political will to implement control programs is also necessary but is often lacking in societies that lack cohesion and where social and economic chaos prevail. Meanwhile, failure to use classic public health measures while waiting for a 'miraculous' system of cure will retard progress. Because of the complexity and cost of controlling infectious diseases, the worldwide burden caused by parasitic infections is only likely to decrease in the context of both social and economic development.

Epidemiology of parasitic infections

ROY M. ANDERSON

Introduction	1	Control of infection and disease	14
Basic concepts	2	Conclusions	16
Transmission dynamics	7	References	16

INTRODUCTION

Epidemiology is the study of patterns of infection and associated disease within populations or defined communities. It is interdisciplinary in character, drawing on concepts and methods from a wide variety of biomedical fields including molecular biology, immunology, genetics, population biology, statistics, and mathematics, plus the specific fields associated with a particular infection, such as virology, bacteriology, parasitology, and vector biology. It is a quantitative field of medicine relying on accurate surveillance and measurement of infection plus disease, and dependent on statistical methods for hypothesis testing, parameter measurement, and description, plus mathematical techniques for the provision of a theoretical template to facilitate the interpretation of observed pattern or experimental outcome. A sound and detailed knowledge of the biology of the host and infectious agent, however, is an essential prerequisite for the successful application of such quantitative tools.

The past decade has witnessed significant changes in the manner in which epidemiological research is conducted, largely arising from the availability of new methods of measurement or detection of infection or disease linked to rapid advances in the disciplines of molecular biology and immunology. One example is the use of polymerase chain reaction (PCR) methods to detect the presence of very low concentrations of a particular pathogen within the human host. Such techniques enable quantitative measures to be made of parasite load or burdens within infected patients, in addition to the more precise determination of the prevalence (proportion of hosts infected) of infection. New immunological tools greatly facilitate the detection of current or past infection with non-invasive sample collection procedures (such as saliva-based assays for antibodies specific to viral, bacterial, and parasite infections) being of particular value in field-based studies.

Advances in other areas have also made very important contributions to epidemiology, particularly in the field of genetics. Molecular methods and the increased availability of genome sequence data for both pathogen and host open new avenues for the study of the determinants of pathogenesis and the coevolution of the parasite and its human or vector host. Increasingly, linkage or segregation analyses are beginning to find associations between the occurrence of disease, or persistent infection, and particular genotypes within human populations. Molecular or genetic epidemiology will undoubtedly be a major growth area in the coming decade. Associated population genetic studies can define the frequency of predisposition to infection or disease within defined populations.

There has also been a growing realization amongst researchers in this area that conventional statistical approaches to epidemiology, which have been so successful in improving understanding of non-infectious disease problems, are less appropriate for the study of the population level consequences of infection and immunity. Increasingly, concepts and methods that have evolved in evolutionary biology, ecology, and population genetics are being used to study the population biology, transmission dynamics, and evolution of infectious diseases within human communities. Such approaches recognize that the interaction between parasite and host

is a very dynamic one, in terms of transmission and persistence, and of the evolution of both organisms (with that of the pathogen having the potential to take place much more rapidly than that of the human host).

Observed patterns of infection and disease in human communities are determined by the interplay between the variables that control susceptibility to infection, its typical course, and the likelihood of serious disease within an individual, and the variables that control the rate of transmission between people. The former include innate susceptibility, the distribution of latent and infectious periods plus the duration of acquired immunity, while the latter include behavioral, social, environmental, and demographic factors. Researchers are typically concerned with the recondite biological and clinical details that make each infection unique. This chapter focuses on the principles that determine observed epidemiological patterns, independent of the type of infectious agent under study. Historically, work on infectious disease is often compartmentalized into distinct areas based on the taxonomy of the infectious agent, namely, virology, bacteriology, and parasitology. However, the principles governing the spread, persistence, and evolution of all infectious agents are the same. A simple example is provided by the notion of reproductive or transmission success. If we consider the host as the basic unit of study, then the reproductive number of an infection (R_0) is the average number of secondary cases of infection generated by one primary case in a susceptible host population (Anderson and May 1991). The magnitude of this parameter reflects the potential for transmission and evolution, and the degree to which control measures must inhibit transmission if an infection is to be eradicated in a given population.

The real world is of course replete with complications – economic and social as well as biological – and it is easy to lose sight of generalities when grappling with the details that ultimately make each infectious agent unique. However, it is often the case in epidemiology that the influence of a few factors dominates the generation of observed pattern. Understanding the key principles that underpin spread and persistence helps in the identification of these factors.

This chapter highlights the key processes that influence the transmission, persistence, and control of protozoan and helminth parasites with a focus on malaria, intestinal nematodes, schistosome flukes, and the filarial worms. Bear in mind, however, that the principles are equally relevant to the study of viral and bacterial infections (Anderson and May 1991).

BASIC CONCEPTS

Microparasites and macroparasites

A distinction is made between microparasites and macroparasites to cut across conventional taxonomic lines in order to focus on the population biology of the infectious agent.

MICROPARASITES

Microparasites may be thought of as those agents which have direct reproduction – usually at very high rates – within the host (Anderson and May 1991). They tend to be characterized by small size and a short generation time. Recovery from infection is usually associated with acquired immunity against reinfection with the same strain of parasite for some time, and often for life. For many viruses, bacteria, and protozoa, however, immunity may be highly strain specific although a degree of cross-protection may arise via shared antigens. Although there are important exceptions, the duration of infection is typically short relative to the expected life span of the human host. This feature, combined with acquired immunity, means that microparasite infections are typically of a transient nature in individual hosts. Most viral, bacterial, and (in a less certain manner) many protozoan parasites fall broadly into the microparasitic category.

For such infectious agents, it makes sense to stratify the host population into a few classes namely: susceptibles, infecteds but latent (i.e. non-infectious), infecteds and infectious, and immune individuals. A reasonable operational definition of a microparasite is an organism whose population biology can, to a sensible first approximation, be described by such a compartmental model. An essential feature of the framework is that no account is taken of the degree or severity of the infection (i.e. the abundance of the infectious agent within the host). The reality of heterogeneity between individuals with respect to genetic background, behavior, and environment is replaced by the abstraction of some average 'infected' or 'immune' individual.

It is often necessary to distinguish between infection and disease. The period between the point of infection and the appearance of symptoms of disease is termed the incubation period. The duration of symptoms of disease is not necessarily synchronous with the period during which an infected host is infectious to susceptible individuals. Furthermore, the host may be infected but not infectious. The period from the point of infection to the beginning of the state of infectiousness is termed the latent period. For some infections such as malaria, intermittent bouts of infectiousness may occur. For others, such as *Human immunodeficiency virus* (HIV), the degree of infectiousness may vary widely throughout the incubation period. The sum of the latent and infectious periods is referred to as the average generation time of the infection. The term average refers to the fact that latent, infectious, and incubation periods are often very variable between individuals due to a variety of factors such as host and parasite genetic background and the size of the infecting inoculum of the infectious agent.

Most epidemiological and demographic parameters – human birth and death rates, disease-induced death rate, recovery rates, rate of loss of immunity – can be measured directly by appropriate observational studies. The transmission rate, however, combines many biological, social, and environmental factors, and is thus rarely amenable to direct measurement. The best way is to infer this rate indirectly via longitudinal or cross-sectional cohort based studies to directly measure the incidence of infection.

MACROPARASITES

Macroparasites may be thought of as those having no direct reproduction within the definitive host. This category embraces helminths and arthropods, where transmission stages produced within or on the host pass to the exterior to complete development to the next stage of often complex life cycles which may involve more than one host (e.g. the schistosome flukes and the filarial worms). Macroparasites are typically larger than microparasites and have much longer generation times, often being an appreciable fraction of the human host's life span. When an immune response is elicited, it usually depends on the past and present number of parasites harbored, and tends to be of a relatively short duration once parasites are removed (e.g. by chemotherapy) from the host. Thus, macroparasitic infections are typically persistent in character, with hosts continually being reinfected. The evocation of an immune response and the pathology induced by infection both depend on the burden of parasites harbored by the host. This means that to quantify levels of infection and morbidity in the population it is necessary to measure the distribution between individuals of parasite numbers per host. As shown in Figure 1, parasite numbers are rarely uniformly or randomly distributed. Typically, the distributions are highly heterogeneous with most people harboring few parasites and a few harboring many. Compartmental models based on divisions into susceptible and infected persons are therefore inappropriate descriptions of the epidemiology of macroparasitic infections. The appropriate framework for study is one that records the prevalence (fraction infected) of infection, the average intensity of infection and the distribution of parasite numbers within the human population.

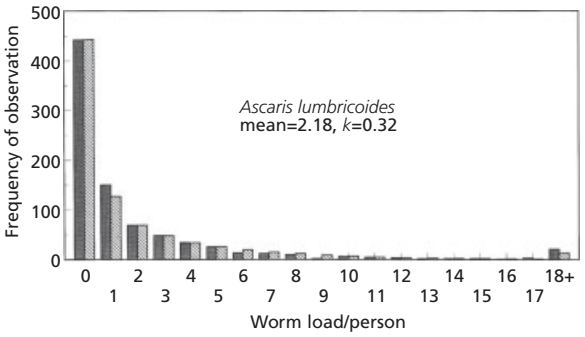

Figure 1 *The frequency distribution of* Ascaris lumbricoides *in a fishing community in Pulicat, Tamil Nadu, India (after Elkins et al. 1986). The negative binomial probability distribution provides a good empirical description of the observed pattern with mean = 2.8 worms per person and* k *= 0.32. Dark bars, observed value; hatched bars, expected value*

The division into microparasites and macroparasites is rather crude. Many infectious agents are not easily forced into this dichotomous scheme. Many protozoan parasites such as the *Plasmodium* species that induce the disease malaria may, to a good approximation, have their epidemiology described by a microparasitic compartmental framework (i.e. prevalence of infecteds, susceptibles, and immunes), although their patterns of persistence within the human population, with individuals being repeatedly infected, are characteristic of macroparasites. However, the dichotomy serves as a useful starting point for highlighting the population biology and epidemiology, as opposed to emphasizing conventional taxonomic categorizations.

Basic reproductive number of infection, R_0

For a microparasite, the basic or case reproductive rate, R_0, is defined as the average number of secondary cases of infection produced by one primary case in a susceptible population. When a microparasitic infection first invades a human community, the fraction susceptible decreases over time. Eventually, some sort of equilibrium state is reached (endemic infection) which may involve oscillatory fluctuations in prevalence or incidence of a seasonal or longer term nature. At this equilibrium (or oscillating equilibrium) the rate at which susceptible infants or children are infected is exactly balanced by the rate at which new susceptibles are born into the community and each infection will on average produce exactly one secondary case. That is, at equilibrium, the effective reproductive rate $R = 1$. If we assume that the human community mixes homogeneously (independent of age, sex, residence location, etc.), the effective reproductive rate R is equal to the basic reproductive rate, R_0, discounted by x, the fraction of the human community that is susceptible, R, is equal to R_0x. Given that at equilibrium $R = 1$, then

$$R_0 = 1/x \qquad (1)$$

where x is the fraction susceptible at equilibrium. This simple relationship provides a method of estimating the value of R_0 from serological or other data on age-specific susceptibility.

For a macroparasite, R_0 is the average number of female offspring (in the case of a dioecious parasite), produced throughout the lifetime of a mature female parasite, which themselves achieve reproductive maturity in the absence of density-dependent constraints. In the absence of these constraints, which include competition

for space or other resources within the human host and acquired immunity dependent on parasite load, parasite numbers within the population would grow exponentially provided $R_0 > 1$. In practice, macroparasite populations tend to be rather stable through time and a variety of density-dependent factors act to generate such stability.

For most common viral and bacterial infections and some protozoa (e.g. *Toxoplasma*), serological tools are available to establish whether or not a person has acquired and recovered from infection at some time in their past. Age-stratified cross-sectional serological surveys or longitudinal cohort studies provide the best information for estimating the magnitude of R_0 in a given community. A diagrammatic serological profile is shown in Figure 2. The magnitude of R_0 can either be estimated from this profile by calculating the fraction of the total population susceptible to infection or equally simply from the following expression:

$$R_0 = (L - M)/(A - M) \qquad (2)$$

where L is life expectancy, M is the average duration of maternal antibody-derived protection (typically 6 months for many common viral infections such as measles), and A is the average age at infection. The key quantity is A, which can be estimated directly from the serological profile (Grenfell and Anderson 1985). If the value of A is small, R_0 is large, and the infection has high transmission efficiency, while, conversely, if A is large, R_0 is small, and the infection has low reproductive success. Transmission success of a given parasite can vary widely in value between different locations and at different times of the year.

Serological surveys provide a wealth of information about the transmission dynamics of infectious agents. They not only provide information on the values of M (duration of maternally derived protection) and A (average age at infection), but they can also guide decisions on the optimum age at which to vaccinate and on the fraction who should be immunized to block transmission. Carrying out large-scale surveys to include infants, children, and adults can be difficult if blood samples are required to extract serum for the evaluation of the presence or absence of antibodies specific to particular antigens. Techniques based on the testing of saliva for secreted antibodies (Perry et al. 1993) have been developed for a variety of infectious agents and these provide epidemiologists with a powerful tool for the study of transmission. Serum or saliva samples must be collected at random within the community, taking due note of important stratifications within the population such as age, sex, ethnic background, residence location, etc. However, problems can arise if the duration of measurable antibody production following infection is not lifelong. This is thought to be the case for many bacterial and protozoan infections which makes serological surveys of less value in determining past and current patterns of transmission. We require more sophisticated techniques to detect immunological markers of past infection with antigenically variable parasitic organisms. In general, however, the collection of serological data, finely stratified according to age, is of vital importance in any quantitative assessment of transmission and the potential impact of control measures. Ideally, age-stratified cross-sectional surveys should be conducted each year, such that a profile of herd immunity can be constructed prior to and post the introduction of any intervention program.

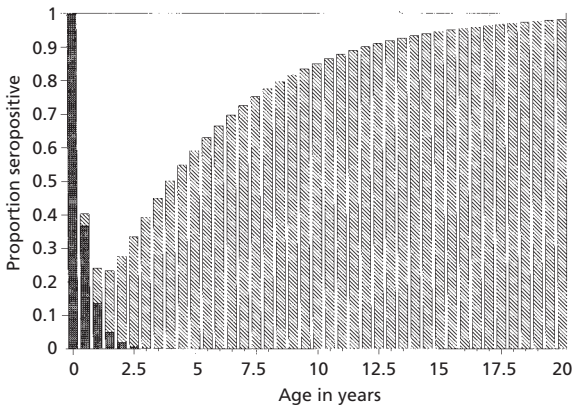

Figure 2 *Diagrammatic representation of a cross-sectional seroepidemiological survey, stratified by age, for the presence of antibodies specific to parasite antigens. Dark bars, maternal antibodies; hatched bars, antibodies from infection*

The measurement and interpretation of the magnitude of R_0 can be made complicated by genetic variability within the parasite population when such variability is reflected by different phenotypic properties such as transmissibility or antigenic characteristics (Gupta and Day 1994). Consider a protozoan that induces lifelong immunity in those who recover from infection. In such cases R_0 is inversely related to the average age at infection, A, by a simple relationship

$$R_0 = L/A \qquad (3)$$

where L is human life expectancy. However, lifelong immunity is rarely observed in parasitic protozoa due largely to the existence of many distinct antigenic strains of a particular parasite species. In such cases, recovery from infection by one strain may or may not confer a degree of resistance to another strain depending on their degree of 'antigenic' relatedness. Immunity may then only develop as a consequence of exposure to many different antigenic types or strains circulating in a given locality. This appears to be the case for the malaria parasite *Plasmodium falciparum*. Young children in hyperendemic malaria zones may experience many clinical attacks of malaria per year (Greenwood et al. 1991). Although older children develop a functional but non-sterilizing immunity manifest as a reduction in clinical episodes, a substantial reduction in parasite load is only

observed in adults after a long period of exposure to the genetical diverse population of parasites. If the delay in the development of immunity is a direct consequence of the antigenic diversity within the parasite population (as opposed to parasite evasion or modulation of the host's immunological attack) then we would expect to see a slower rise by age of immunological (seroepidemiology) evidence of exposure to a particular strain, but a much faster rise in the exposure to 'malaria', where the latter is defined as the experience of any one of several strains. When n strains are independently circulating in a defined population, the average age on first exposure to malaria, A_n, is

$$A_n = 1/\sum_{i=1}^{n} R_{0i} \qquad (4)$$

Here it assumed that strain-specific immunity is life-long and R_{0i} defines the case reproductive number of strain i. This equation makes clear that a low average age at first infection (often the case for *P. falciparum*) can arise when the transmissibilities of each of many strains circulating is low. These conclusions are well supported by field observation on the rise with age in the fraction of a population in Madang, Papua New Guinea who had experienced infection with five antigenically distinct strains of *P. falciparum* (Gupta et al. 1994b) (Figure 3).

The relationship between prevalence and intensity of infection

We have briefly noted that many sources of heterogeneity influence the distribution of parasites within a human community (Figure 1). The precise degree of heterogeneity, measured either by a statistic such as the variance/mean ratio (V/M) of parasite load per host, or the aggregation parameter, k (which varies inversely with the degree of aggregation) of the negative binomial probability distribution (which provides a good empirical model of many observed distributions), determines the relationship between the prevalence and mean intensity of infection (Figure 4a). As the degree of contagion or aggregation increases, the prevalence reaches a plateau, well below 100 percent, as the mean parasite load rises. For a given species of parasite, observed patterns of heterogeneity are often remarkably constant independent of the study community or geographical region (Anderson and May 1985, see Figure 4b). For helminth parasites in particular, worm load is directly correlated with the likelihood of symptoms of disease. As such parasite aggregation determines the prevailing burden of disease in a given population for a fixed mean worm load, the greater the degree of parasite aggregation, the smaller the number of individuals in the population showing symptoms of disease. However, for extreme aggregation the severity of disease will be greater in those showing symptoms due to their very high worm loads.

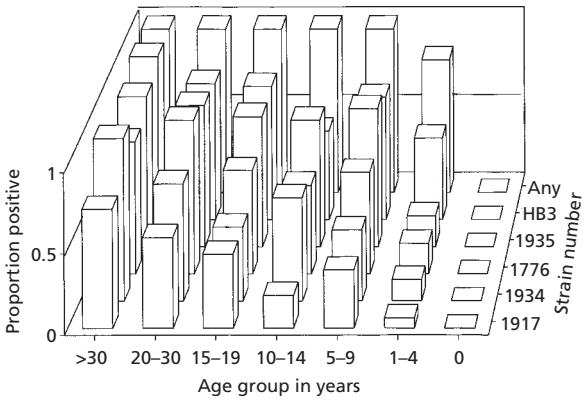

Figure 3 *Age-stratified serological survey for presence of past infection by a series of distinct isolates or strains (serotypes) of* Plasmodium falciparum *from a community in Papua New Guinea (data from Gupta et al. 1994b). The isolates differ in parasite induced erythrocyte surface antigens (PIESA). The proportion exposed to any type is recorded at the back of the graph (= Any)*

Heterogeneity and predisposition to infection

The epidemiological measures of prevalence and average intensity of infection are summary statistics of the frequency distribution of parasite numbers per host (Figure 1). The form of these distributions is of great significance to the burden of disease in a population and the regulating constraints acting on the net rate of parasite transmission. For helminths and protozoa, the distributions are highly aggregated or contagious in form such that most individuals harbor few parasites and a few individuals harbor many. In other words, the variance in parasite load is much greater in value than the mean.

Parasite aggregation may arise as a consequence of a wide variety of factors, either acting alone or concomitantly (Anderson and Gordon 1982). These include heterogeneity in exposure to infection (due to social, environmental, or behavioral factors, or to aggregation in the spatial distribution of infective stages or infected intermediate hosts), differences in susceptibility to infection (due to genetic or nutritional factors, or to varying past experience of infection), or to variability in parasite survival within different individuals (due to genetic, immunological, or nutritional factors). Which factors are of major importance as determinants of observed patterns is often difficult to ascertain in particular settings. Heterogeneity in the human behavioral patterns associated with exposure to infection is often very important as is well illustrated by water contact patterns in relation to *Schistosoma mansoni* transmission (Fulford et al. 1996) (see Figure 6, see p. 7). However, host genetic background is undoubtedly of greater impor-

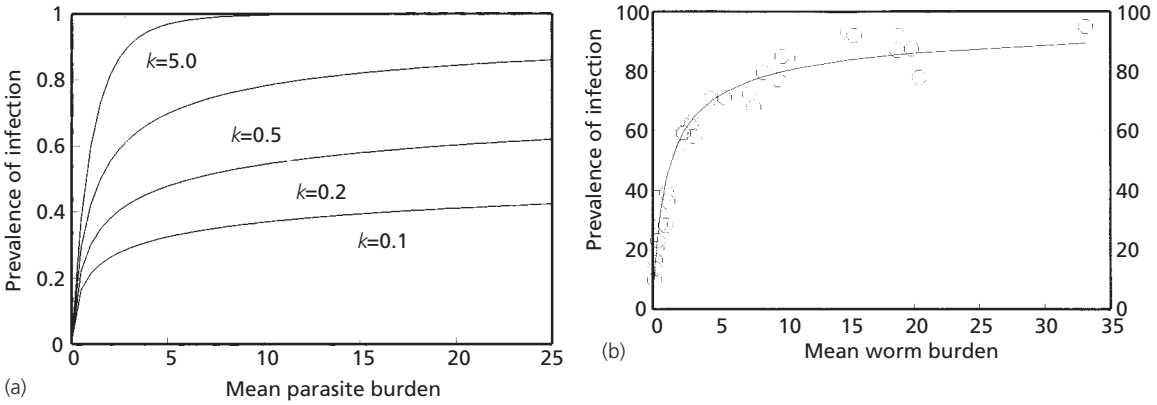

Figure 4 (a) *The relationship between the prevalence and mean intensity of infection predicted by the negative binomial distribution for different values of the aggregation parameter* k *(where* k → *0 reflects extreme aggregation and* k → *5 reflects a random distribution of parasite numbers per host).* **(b)** *A comparison of the observed and expected (on the basis of the negative binomial model with* k = *0.586) relationship between the prevalence and intensity of infection with* Ascaris lumbricoides *in different human communities. The circles represent observed values; the continuous line is the expected value (after Guyatt et al. 1990).*

tance as well illustrated by the practice of using inbred strains of rodent hosts in the experimental study of many parasitic infections in order to reduce variability in the typical course of infection.

A growing number of studies are pointing to genetic factors in human communities as key determinants of susceptibility to infection and disease. For example, severe clinical disease in schistosomiasis is typically the consequence of heavy infection, the occurrence of which is determined largely by the susceptibility or resistence of individuals (Wilkins et al. 1987). The intensity of infection in a particular study site in Brazil has been shown to be influenced by a major gene leading to the hypothesis that worm burden is largely controlled by the genetic background of the human host concomitant with the degree of exposure to infection (Abel et al. 1991). The gene, referred to as *sm1*, is located on chromosome 5, and the region in which segregation analysis indicates it lies contains several candidate genes that encode immunological molecules that are known to play important roles in the acquisition of resistance to *S. mansoni* (Marquet et al. 1996).

The discovery of a clear genetic marker for predisposition to heavy infection in the study of Marquet et al. (1996) in the case of schistosomes may point the way to a better understanding in general of predisposition to helminth infection and associated disease. Epidemiological studies based on the quantification of worm load, chemotherapeutic treatment, and the monitoring of patterns of re-infection post treatment, have provided firm evidence of predisposition to heavy infection for a variety of parasites including *Ascaris lumbroides* (Elkins et al. 1986), *Necator americanus* (Schad and Anderson 1985), *Trichuris trichiura* (Bundy et al. 1987), and *Schistosoma mansoni* (Bensted-Smith et al. 1987). Undoubtedly, however, genetic factors act concomitantly with the host behaviors to determine parasite load.

Aggregated distributions of parasite numbers per host are also of importance for protozoans such as the malarial parasites. Observed heterogeneities include the distribution of oocysts in mosquito populations, the number of distinct antigenic types or strains per human host or per mosquito, and the frequency distribution of mosquito bites per person (Paul et al. 1995; Dye and Hasibeder 1986; Anderson 1994). If there is significant heterogeneity in exposure/susceptibility to infection then in epidemic situations, the fraction of the population infected will depend critically on the degree of heterogeneity in exposure. This point is illustrated in Figure 5 which records the relationship between the fraction infected in an epidemic and the magnitude of transmission success of the parasite (R_0), as a function of the degree of heterogeneity in the rate of exposure to infection defined by the coefficient of variation (where cv = 0

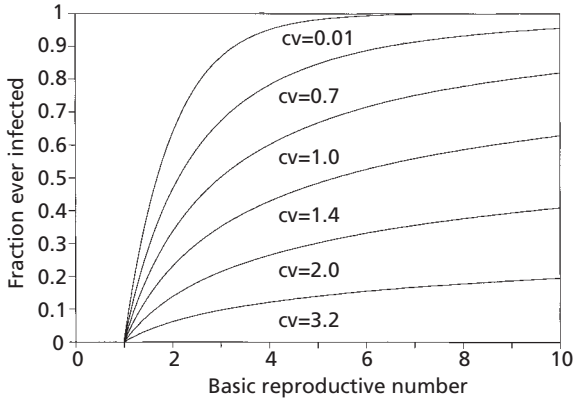

Figure 5 *The predicted relationship between the fraction of a population infected by a microparasite over the course of an epidemic in a virgin population and the degree of heterogeneity in the human behaviors that dictate exposure to infection as measured by the coefficient of variation (cv) where cv = 0 reflects a random distribution (see Anderson and May 1991).*

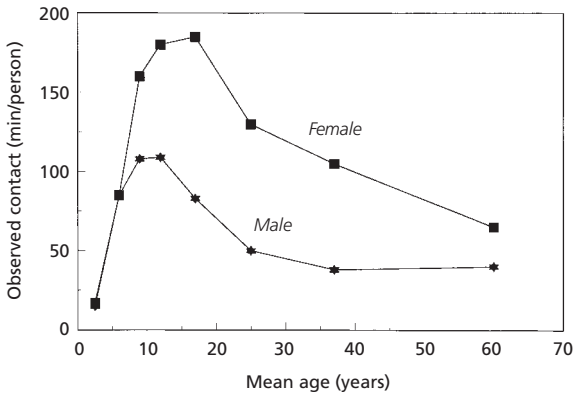

Figure 6 *Recorded water contact rates, stratified by age and sex in a Kenyan community where* Schistosoma mansoni *is endemic. The vertical axis records the arithmetic mean duration of water contact per individual (Kintengei community (1990–1992), after Fulford et al. 1996).*

reflects a random distribution of exposure) of the frequency distribution. An example of variation in exposure to infection is shown in Figure 6.

Irrespective of the generative mechanisms of such patterns, aggregation of parasites within human communities has important implications for the epidemiology and control of these infections. Firstly, it enhances the likelihood of an individual parasite finding a mate of the opposite sex (Figure 7). It therefore enhances the net reproductive rate of the total parasite population. Second, it increases the net regulatory impact of density-dependent constraints on parasite establishment, survival, and reproduction (often immunologically mediated). Third, it results in severe symptoms of disease typically occurring in a relatively small fraction of the total population. Finally, it has important implications for the design of control programs (i.e. chemotherapy can be focused on those predisposed to heavy infection).

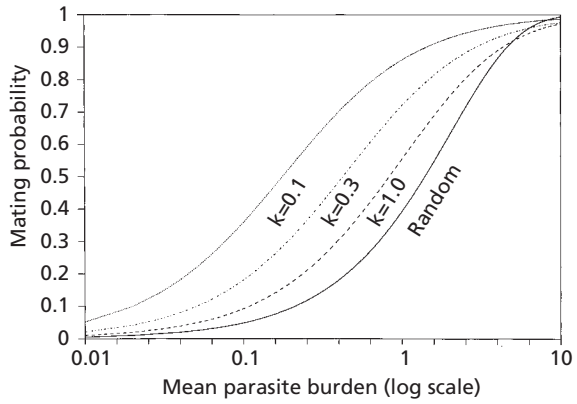

Figure 7 *The dependence of the probability that a female worm is mated, on the mean worm burden per person, for various assumptions concerning the distribution of parasite numbers per host for a monogamous parasite. The distributions are the negative binomial (= aggregated) with various* k *values and the Poisson (= random) distribution (after May 1977).*

If host genetic background has a major influence on immunocompetence, however, as suggested by work on *S. mansoni* (Marquet et al. 1996), then work towards vaccine development must take account of the fact that the aim of immunization must be to protect those least able to acquire immunity.

TRANSMISSION DYNAMICS

Observed epidemiological pattern is generated by the population or transmission dynamics of the parasite within a defined community. Before turning to the key processes influencing transmission, a brief comment is made on observed patterns of prevalence and intensity of infection.

Cross-sectional surveys of prevalence and intensity of infection

A variety of methods may be employed to assess the manner in which the prevalence or intensity of infection changes over time or between different strata (such as age groups) of the population, depending on the type of infectious agent under study. These range from molecular and immunological methods to the direct counting of either parasite eggs in fecal material (intestinal nematodes) or infected red blood cells in blood samples (i.e. for *Plasmodium*). The majority of published studies are cross-sectional and stratified by age owing to the long period of study required to monitor longitudinal changes in a cohort of people over their average life span.

As illustrated in Figures 8–10, changes in both prevalence and intensity with age (= time) are typically convex in form with the latter showing a greater degree of convexity than the former. Changes in prevalence as individuals age are a poor reflection of average parasite load due to the high degree of heterogeneity in the frequency distribution of parasite numbers per person. Convex patterns of change with age may arise either as a result of age-related changes in exposure to infection (due to behavioral factors) (see Figure 6) and/or increased resistance to infection (where acquired immunity may influence establishment or parasite survival once in the host) in older individuals with considerable past experience of infection. With respect to convexity in prevalence an additional factor may be of importance. A decay in prevalence in older age groups could arise, independent of any change in the average worm load, if the degree of parasite aggregation increases with age. Much evidence supports this notion and it may arise due to heterogeneity in genetic make-up within the host population where some individuals develop a good degree of immunity after limited exposure while others remain predisposed to heavy infection. In general, convexity is a common feature for all of the major

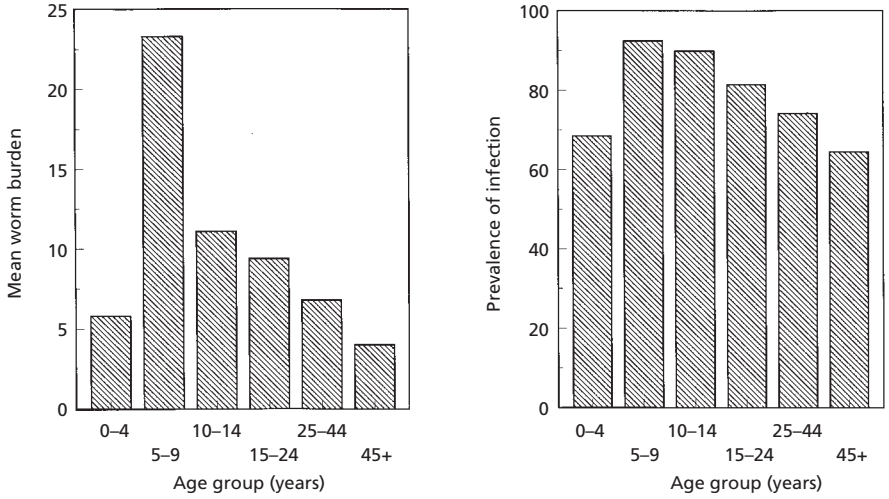

Figure 8 *Cross-sectional survey of the prevalence of infection and mean worm burden in a community in southern India infected with the intestinal nematode* Ascaris lumbricoides *(after Elkins et al. 1986)*

parasitic infections and may arise from ecological (= behavioral) or immunological processes, or a combination of both.

Studies in which age-related changes in exposure have been quantified (i.e. water contact patterns in the case of schistosomes, vector biting rates for malaria and the filarial worms) suggest that a combination of both factors acts to determine the observed convex profiles. A good indication of the significance of the slow build up of immunity with repeated exposure as individuals age is provided by comparative studies of the degree of convexity as a function of the overall net intensity of transmission in a defined community. For intestinal nematodes (Anderson and May 1991), schistosomes (Anderson 1987), and malaria (Boyd 1949), the degree of convexity is greater in areas of high transmission intensity and less in areas of low average exposure (Figure 11). The issue of why immunity to parasite infection builds up slowly as individuals age is discussed later in this chapter.

In summary, observed patterns of infection with parasitic organisms tend to reveal three key points, namely, heterogeneity in parasite burdens per person, predisposition to heavy or light infection, and convexity in the manner prevalence or intensity change as individuals age.

Life cycles and reproductive success

Microparasite and macroparasite life or developmental cycles may be direct or indirect. In the latter case one or more intermediate hosts may be involved, such as the molluskan intermediate host of the schistosomes and the mosquito vector of the malaria parasites. The transmission potential of a parasite with a complex life cycle is determined by many distinct population-determining

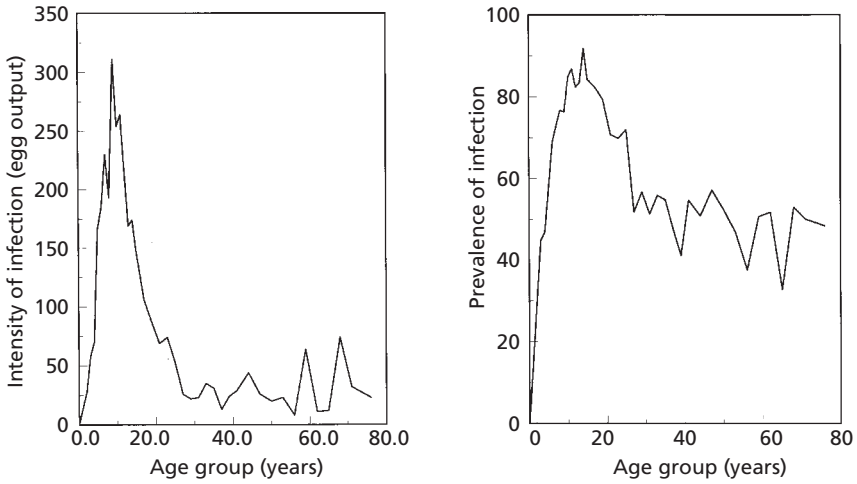

Figure 9 *Cross-sectional survey of the prevalence of infection and the mean intensity of infection (based on fecal egg counts) in a community in Tanzania infected with* Schistosoma haematobium *(after Bradley and McCullough 1973)*

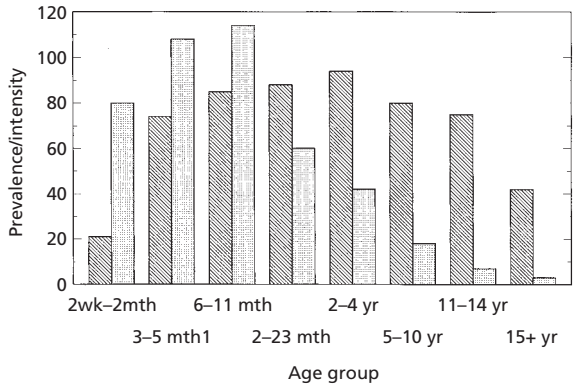

Figure 10 *Cross-sectional survey of the prevalence (dark bars) and intensity (lighter bars) of* Plasmodium falciparum *(after Davidson and Draper 1953)*

rate processes that influence the many distinct developmental stages. Examples of the population and rate processes involved in some direct (intestinal nematodes) and indirect cycles are portrayed in Figures 12–14.

The overall transmission or reproductive success is best defined by the basic reproductive number, R_0, of the parasite. For a direct life cycle intestinal nematode with a free-living larval or egg stage as the transmission stage (Figure 12), the magnitude of R_0 in a human community of size N is defined as follows (see Anderson and May 1991):

$$R_0 = [s\lambda\beta N d_1 d_2]/[(\mu + \mu_1)(\mu_2 + \beta N)] \qquad (5)$$

The individual parameters are defined in Table 1. Provided $R_0 > 1$, the parasite population will persist in the host population. However, unlike many directly transmitted viral or bacterial infections, the critical host density for persistence of most protozoa and helminths is typically very low. Infections such as intestinal nematodes or malaria parasites were therefore able to persist endemically in small hunter-gatherer societies in areas such as the Amazon basin or Papua New Guinea (Tyrrell 1977) prior to the encroachment of civilization into remote rain forest habitats.

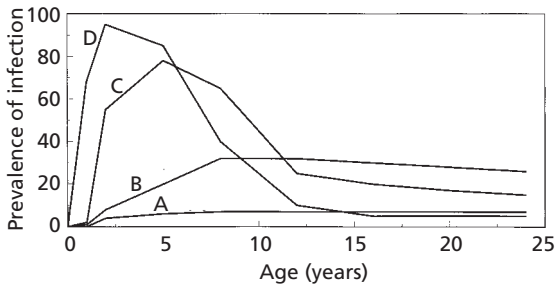

Figure 11 *Prevalence of acute malaria infection versus age in years in populations with differing levels of endemicity. A, low endemicity; B, moderate endemicity; C, high endemicity; D, hyperendemicity (after Boyd 1949)*

In the absence of regulating constraints on population growth, the parasite population growth rate Λ is given approximately by:

$$\Lambda = (R_0 - 1)/(\mu^{-1} + \mu_1^{-1}). \qquad (6)$$

This expression makes clear the role of net reproductive success (R_0) and adult parasite life expectancy μ_1^{-1} as important determinants of re-infection rates, or parasite population recovery, after the cessation of control measures. Populations of short-lived parasites (i.e. malaria) will bounce back rapidly to pre-controlled levels once control measures cease, while long-lived species may take many years to recover (Table 2).

For microparasites with indirect life cycles (Figure 14) such as the *Plasmodium* species, the magnitude of R_0 is determined by rate processes acting on the human and vector populations. For malaria R_0 is defined as follows (see Aron and May 1982):

$$R_0 = [ma^2bc/\mu_2\gamma]exp(-\mu_1 T_1 - \mu T_2) \qquad (7)$$

where m is the ratio of female mosquitoes per human host, a is the rate of biting on humans by a single mosquito (the 'human biting rate' defined as the number of bites per unit of time), b is the proportion of infectious bites that produce a patent infection, γ^{-1} is the average duration of infectiousness over the course of infection in the human host, c is the proportion of bites by a susceptible mosquito on infected people that produce a patent infection in the vector, μ_1^{-1} is mosquito life expectancy, μ_2^{-1} is human life expectancy, T_2 is the latent period in the mosquito (before it becomes infectious to humans), and T_1 is the latent period in humans (before gametocytes appear) (Table 3). In practice, the effective time the insect vector has to transmit is much shorter than its life expectancy due to the fact that the latent period of infection in the vector is often long by comparison with life expectancy (Table 3). This is the reason why the prevalence of infection in vectors is often very low (a few percent or less), since few survive long enough for the infection to mature. If $R_0 > 1$, the infection is endemic in the human population.

Vector densities often fluctuate widely over the different seasons of a year due to the influence of environmental factors, such as rainfall on breeding success and life expectancy. The magnitude of m in eq. (5) may therefore fluctuate widely such that at certain times of the year $R_0 > 1$, whilst at others (the dry season) it falls below unity in value. In such circumstances the endemic persistence of malaria depends on the survival of the infection in the human host. Areas of low transmission are much more sensitive to seasonal changes in mosquito or vector density.

More generally, the longest lived stage in the parasite's life cycle plays a key role in ensuring the long persistence of the organism. Control measures aimed at

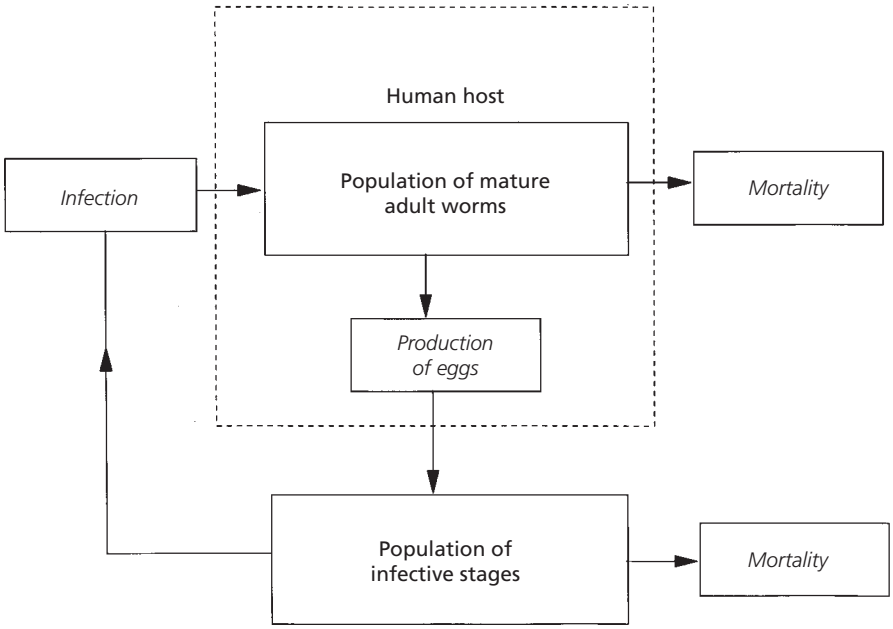

Figure 12 *Flow chart of the principal population and rate processes involved in the life cycle of a directly transmitted intestinal nematode (macroparasite)*

different stages in the cycle (e.g. insecticides acting on the vector or chemotherapeutic agents acting on the infection in the human host) may have similar effects on transmission success, but very different effects on the ability of the parasite population to recover rapidly post the cessation or interruption of control measures.

Regulating constraints on parasite population growth

A characteristic of many parasitic infections is their stability or robustness to perturbation, whether induced by environmental changes or control interventions.

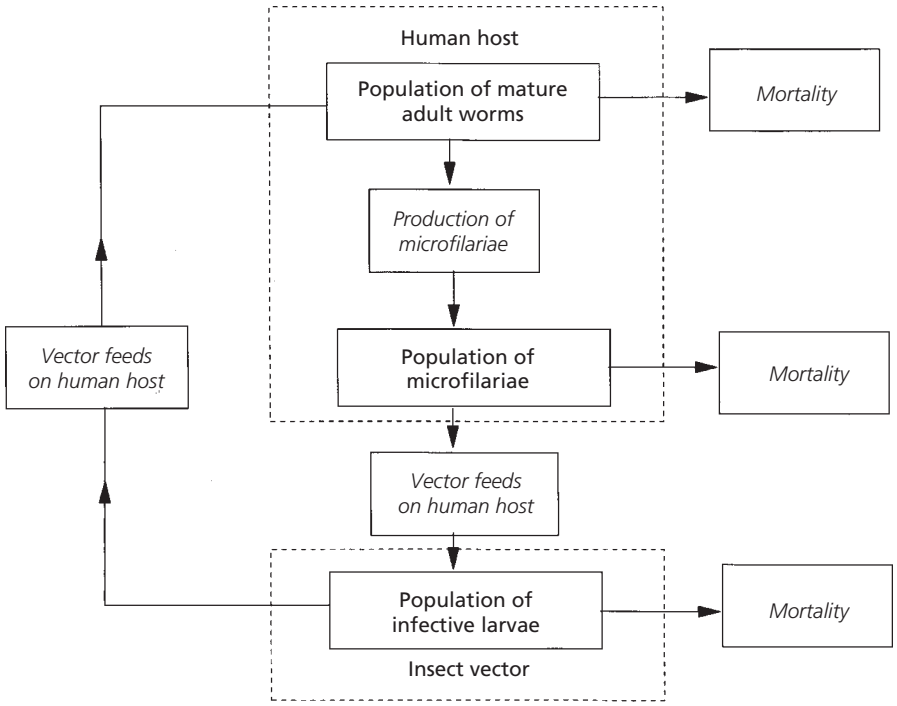

Figure 13 *Flow chart of the principal populations and rate processes involved in the life cycle of an indirectly transmitted filarial nematode (macroparasite)*

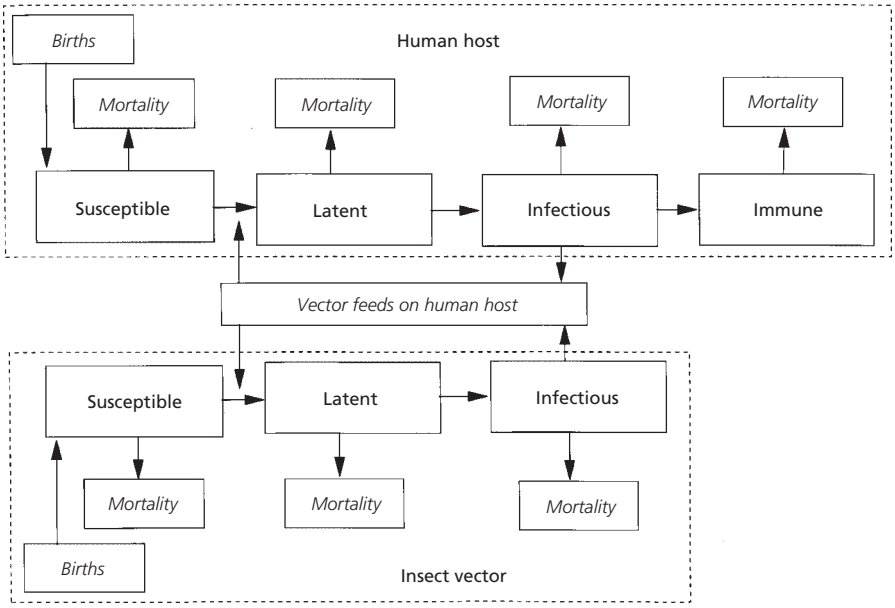

Figure 14 *Flow chart of the principal population and rate processes involved in the life cycle of a malarial parasite (vector transmitted microparasite)*

Helminth infections are particularly remarkable in this sense, where after the cessation of mass chemotherapy, parasite abundance typically returns, over a time span of a year or so, to pre-control levels. In part this is a consequence of their transmission potential (e.g. very high fecundity) and in part due to the long life expectancy of the mature worms in the human host (Table 2). In the absence of density-dependent constraints on population growth, however, provided $R_0 > 1$, their abundance would grow exponentially. As originally noted by Malthus in the context of human population, resource limitation must eventually regulate the rate of growth until some sort of equilibrium is attained. This may be oscillating in character but for most parasites, if we ignore short-term seasonal fluctuations, endemic states appear to be stable and non-oscillatory. For parasites occupying an environment created by another living organism, the constraints on growth are many and varied and act on establishment, fecundity, and survival. An example is presented in Figure 15, where the fecundity of *S. mansoni* is plotted as a function of the intensity of infection. They may arise via competition for limiting resources such as food or space or, more commonly, as a result of the non-linear action of the host's immunological responses. The non-linear nature of such responses is reflected by modest or little response at very low parasite densities, and strong responses at high densities. At very high parasite (or antigen) densities, in some cases the effectiveness of the immune response decays as depicted in Figure 16, where T cell proliferation in response to different concentrations of *P. falciparum* antigens is plotted. This may be due to modulation by the parasite, the accumulation of parasite

Table 1 *The rate processes that determine the magnitude of the basic reproductive number, R_0, of a direct life cycle intestinal nematode (see Anderson and May 1991)*

Parameter	Definition
s	Sex rate of adult worms
λ	Per capita fecundity of female worms
β	Per capita transmission rate of infective stages to the human host
d_1	Proportion of adult worms that attain sexual maturity
d_2	Proportion of transmission stages that survive to the infective stage
μ^{-1}	Life expectancy of the human host
μ_1^{-1}	Life expectancy of adult worms
μ_2^{-1}	Life expectancy of infective larvae
N	Human population size

Table 2 *Helminth parasite life expectancy in the human host (see Anderson and May 1985 for source references)*

Parasite	Life expectancy (years)[a]
Enterobius vermicularis	<1
Trichuris trichiura	1–2
Ascaris lumbricoides	1–2
Necator americanus	2–3
Ancylostoma duodenale	2–3
Schistosoma mansoni	3–6
Schistosoma haematobium	3–6
Wuchereria bancrofti	3–5
Onchocerca volvulus	8–10

a) Rough approximations, owing to the practical difficulties inherent in estimation.

Table 3 *Latent periods and vector life expectancies (see Anderson and May 1991 for source references)*

Parasite	Latent period (days)	Vector	Life expectancy (days)
Plasmodium falciparum	11 days (24°C)	*Anopheles gambiae*	8–15
Trypanosoma brucei	15–35	*Glossina morsitans*	28–32
Yellow fever virus	10–12	*Aedes aegypti*	8–14
Onchocerca volvulus	14	*Simulium damnosum*	10–20
Wuchereria bancrofti	13–15	*Anopheles funestus*	10–15
Schistosoma mansoni	20–42 (22°C)	*Biomphalaria glabrata*	7–42

secreted toxins or some sort of malfunctioning of the host induced regulatory constraints on the immune response.

Immunity to parasitic infections

One of the major features of the epidemiology of parasite infections is evidence for repeated infection as individuals age in areas of endemic exposure despite abundant evidence of immune recognition and attack. This is a puzzle of both practical and fundamental significance. Protozoa and helminths have complex genomes and elaborate developmental cycles, and have evolved a wide array of mechanisms to evade or modulate immunological attack (Maizels et al. 1993 and Immunology and immunopathology of human parasitic infections).

As mentioned earlier, the observed aggregated distributions of parasite number per host may reflect differences in innate susceptibility to infection or in the ability to mount effective immunological responses. Work on the population dynamics of the interaction between subsets of T helper cells (Th1 and Th2 subsets) suggests that early exposure to infection in infancy (or even in the womb via maternal experience) may in part determine predisposition to heavy or light infection where high exposure generates tolerance with elevated Th2 responses concomitant with high helminth loads (Schweitzer and Anderson 1992). The quantitative details of the host's ability to recognize and respond to particular parasite antigens (influenced by the genetic make-up of the host) is of importance in determining whether the host is persistently susceptible or develops protective immunity.

To tease out the factors that control observed patterns of infection and immunity in communities, epidemiological study must turn more and more to detailed longitudinal studies of changes in parasite numbers and immunological responses specific to parasite antigens. For the blood-dwelling schistosome flukes in humans (*S. mansoni* and *S. haematobium*), circulating specific and non-specific serum IgE correlates both positively with accumulated past experience of infection and negatively with re-infection rates after drug treatment (Hagan et al. 1987). For the gut-dwelling nematode *Trichuris trichiuria*, comparison of age-dependent isotope responses and the age-profile of worm burden in two endemic communities with very different levels of transmission suggests that parasite-specific secretory IgA responses best reflect accumulated past experience of infection, whereas serum IgG isotopes simply correlate positively with current worm burden (Needham et al. 1994) (Figure 17).

How specific immunological responses to protozoa and helminths operate to generate resistance (effector mechanisms) is poorly understood. Some information can be drawn from epidemiological studies via associa-

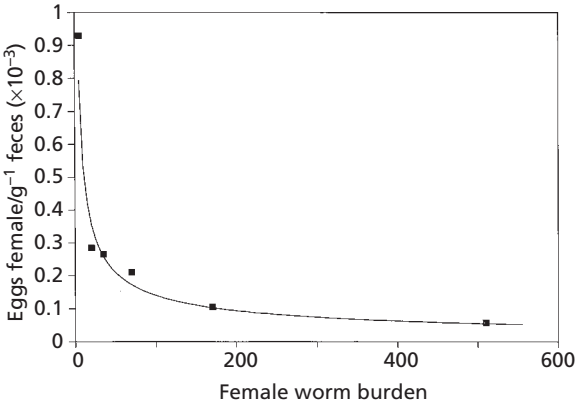

Figure 15 *Density-dependent fecundity in* Schistosoma mansoni *based on autopsy data collected by Cheever (1968) (see Medley and Anderson 1985)*

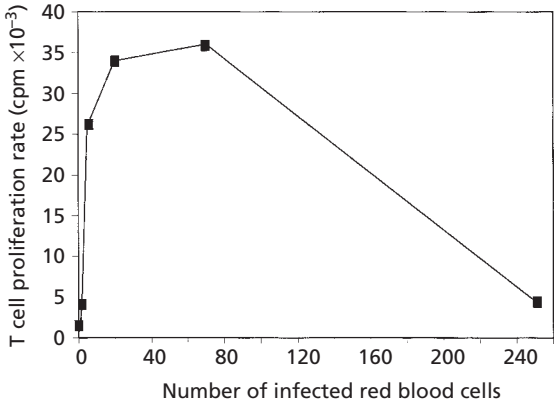

Figure 16 *Dose–response curve of the influence of antigen concentration (number of* P. falciparum *infected red blood cells) on T-cell proliferation rates (after Jones et al. 1990)*

tion of parasite load with different types of response, or by following immune responses following drug treatment and during re-infection. A general pattern seems to be that individual responses mounted to protozoan and helminths rarely operate in isolation and resistance is typically a multi-component response (see Immunology and immunopathology of human parasitic infections).

The many and exciting opportunities presented by advances in molecular biology for the study of immunity to parasites are parallelled by the challenge of an ever-expanding descriptive literature. At present our understanding of how immunity (as reflected by resistance to infection and increased rates of parasite clearance from the host) works for any single protozoan or helminth parasite of humans is limited despite abundant descriptive study (see Immunology and immunopathology of human parasitic infections). The population ecology of the immune system is a very non-linear world and future research will need to emphasize the measurement and quantification of the many rate parameters that control the humoral and cellular responses to parasite antigens, and the functional dependencies between parasite and immune system variables that determine the dynamics of infection both within the host and in the community of hosts. To achieve this for the major infections of human communities will require more detailed longitudinal studies that combine conventional measures of parasite burden with immunological and molecular studies of parasite genetic diversity and the dynamics of immune responses under repeated exposure to infection.

Antigen diversity and strain structure in parasite populations

The maintenance of antigenic diversity is a key strategy adopted by many infectious agents to evade immunological attack in the host and to facilitate the invasion of hosts who have prior experience of infection. Advances in molecular biology have provided many new tools for the study of genetic diversity within parasite populations and these have stimulated a shift in emphasis in epidemiological research towards a more evolutionary approach to the study of infection and immunity. Evolution is at the core of the relationship between host and pathogen. In seeking explanations of observed epidemiological pattern, in the search for new drugs and vaccines, or indeed in the study of immunological responses to infection, the enormous potential of viruses, bacteria, protozoa, and helminths to evolve rapidly (either via mutation or recombination events) on timescales much shorter than the generation time of the human host, is often inadequately appreciated. In many cases, particularly for microparasites, such evolution may take place on a timescale faster than that required to mount an effective immunological response. Genetic variation in microparasites, via antigenic change, is often a central pillar of the pathogen's strategy to persist in the host in the face of immunological attack. Persistence enhances the likelihood of transmission to new hosts in the population. This strategy is particularly common amongst persistent viral or protozoan infections, such as HIV or *Plasmodium* or *Trypanosoma* species, where the immune system acts as the main selective force driving the emergence and reproductive success of 'escape' antigenic variants. One spin-off of the rapidly expanding databases on the antigenic diversity of important human pathogens (sequence databases), has been the development of statistical techniques to examine relatedness between different parasite isolates via the construction of phylogenetic trees (Harvey 1996). These techniques often enable inferences to be drawn (about who acquired infection from whom) via sequence data from parasite isolates from different patients. In the coming decade, sequence information on genetic variation within pathogen populations will increasingly be linked to phenotype, as mirrored by reproductive success of the parasite or the pathogenesis induced by different genetic variants.

At the between-host level, antigenic variation for both the microparasites and macroparasites may permit repeated infection of individual hosts as is evident in *P. falciparum* infection in humans. The slow build up of cross-reactive (across parasite strains) immunological responses after repeated exposure to different antigenic strains will influence the duration of infection, the infectiousness of a person and in some cases the likelihood of the occurrence of disease. In many cases the delay in the development of immunity to parasitic infection may be a consequence of the antigenic diversity of the parasite in which protective immunity only develops after exposure to many different antigenic types or strains circulating in a given locality. The antigenic genetic constitution of a parasite population may vary from one locality to another (Gupta and Day 1994).

Where many strains persist in a given community the question arises of how this diversity is maintained. A

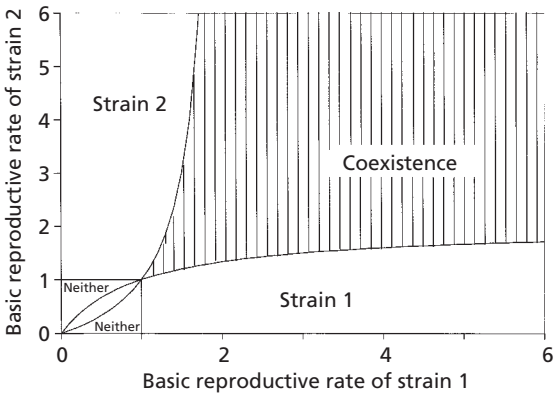

Figure 18 *The influence of the degree of cross-immunity (c = 0, total cross-immunity, c = 1, no cross-immunity, with c set at 0.5) on the pattern of coexistence of two strains of a microparasite as a function of their respective transmission success as measured by the basic reproductive number,* R_0 *(after Gupta et al. 1994a)*

simple view might be that the strain with the greatest reproductive success would, over time, competitively displace other strains. However, recent work shows that this is not necessarily the case, provided a degree of cross-immunity builds up to antigens shared by all strains. In the case of complete cross-immunity, competitive exclusion occurs, while in the case of no cross-immunity (unlikely in reality), all strains can persist since they circulate independently in the host population (Gupta et al. 1994a). For intermediate cases (probably the norm), coexistence is possible provided the reproductive successes (the R_0) of the various strains do not differ too widely in magnitude (Figure 18). Long-term studies of temporal and spatial trends in the prevalence of different parasite strains (e.g. *P. falciparum*, African trypanosomes, and some helminth species) are in progress, but as yet little is understood about longitudinal trends in parasite diversity within defined human communities (Anderson 1994; Snow et al. 1993). What has become clear, however, is that superinfection of an infected host by a new strain appears common for many of the microparasitic organisms, including HIV and malaria (Paul et al. 1995; Robertson et al. 1995).

The observation that many distinct strains persist in human communities over long periods of time raises a further question concerning the role of genetic exchange in the maintenance of parasite strain structure. Many parasites have the opportunity for the exchange of genetic material because of, for example, sexual processes in the case of *P. falciparum*, coinfection of the same host cell for HIV, or transformation in bacteria. The persistence of strain structure plus the frequent opportunity for genetic exchange appears paradoxical, because it would seem that the former would be lost rapidly as a result of genetic recombination. This issue has recently been resolved by theoretical and observational studies which reveal that dominant polymorphic antigenic determinants (that is, those that elicit the most effective immune responses) will be organized into non-overlapping combinations of antigenic determinants as a result of selection by the host's immune system, thereby defining a set of distinctive independently transmitted strains (Gupta et al. 1996). Dominant polymorphic antigen determinants will be in linkage disequilibrium, despite frequent genetic exchange, even though they may be encoded by several unlinked genes. By contrast, weaker polymorphic determinants within the same parasite population will be in linkage equilibrium. This suggests that the detection of non-random association between epitope regions of parasite antigens can be employed as a strategy for identifying the dominant polymorphic antigens. To date, analyses of linkage disequilibrium patterns within infectious agent populations have, for the most part, only addressed the question of clonality (Walliker 1989; Tibayrenc et al. 1990).

The population dynamics and genetics of a parasite population that is structured into strains by a dominant immune response may be influenced at other levels by weaker responses to both conserved and other polymorphic determinants. For example, the typical age distribution of *P. falciparum* prevalence (see Figure 10) suggests that although the variant surface antigens (VSA) (which undergo antigenic variation within the host) categorize the population into strains (each with a given repertoire of expressed antigens), some degree of infection blocking immunity to all strains is eventually established after repeated exposure to a conserved antigen (Gupta and Day 1994).

More generally, these and other studies reveal the importance of a better understanding of the population genetics of parasite and host populations for the interpretation of epidemiological patterns. Molecular epidemiological studies that address the question of the linkage between genetic diversity in the parasite and the incidence of infection and associated disease are likely to be a major focus in the epidemiology of infectious diseases in the coming decade. The occurrence of disease in infected patients may often be linked to the subtle interplay between the genetic background of the host and that of the invading pathogen.

CONTROL OF INFECTION AND DISEASE

At present, the options for the community-based control of the major tropical parasitic infections are either chemotherapy (e.g. for malaria and the helminth infections) or interventions to prevent exposure to infection (e.g. impregnated bed nets to prevent contact with biting vectors, safe water supplies, and good sanitation to reduce contact with the transmission stages of intestinal nematodes). Vaccines are not available for any of the key parasitic infections and early trial results with candidate products have been disappointing. To date, no effective vaccine has been developed for an antigenically

variable infectious agent that provides long protection duration, irrespective of whether the target agent is a virus, bacterium or protozoan. In research on candidate vaccines, most attention is directed at achieving high efficacy. However, duration of protection is of equal significance in terms of potential effectiveness within a community-based immunization program.

For both chemotherapy and interventions to reduce the likelihood of transmission, the difficulty of the task of achieving long-term control is related to the magnitude of the transmission intensity in a defined community as measured by R_0. To block or prevent transmission, the magnitude of R_0 must be reduced to less than unity in value. As control measures are introduced, and the value of R_0 progressively declines over time, significant changes in the prevalence of infection are only likely to occur as the critical point of $R_0 = 1$ is approached (Figure 19).

For microparasite infections, community-based chemotherapy or chemoprophylaxis (in the case of malaria) is expensive and beyond the reach of most communities in poor tropical regions. In addition, treatment tends to select for resistant strains of the parasite, as well illustrated by malaria. In many regions of the world, but particularly in South-East Asia, multi-drug resistant strains of *P. falciparum* are a major cause of morbidity and mortality. Some take a pessimistic view that with the decline in the rate of development of new antimalarials (because of drug development costs and the endemism of the infection in poor developing, as opposed to wealthy developed countries) the battle to control malaria by community-based drug use is likely to be futile in the longer term. As such, many see the future in terms of vaccines although current progress does not promote optimism for rapid advances in this area. The main hope at present lies in an integrated approach involving vector control by insecticides, the promotion of community-wide impregnated bed net use, and drug treatment to prevent mortality (see Control of parasites, parasitic infections and parasitic diseases).

Epidemiological study of the emergence and persistence of drug resistant parasites has been limited in scope and scale to date. Detailed long-term longitudinal studies (ideally cohort based) are required in defined areas to measure the frequency of the genes that determine resistance to defined drugs. In parallel with such molecular epidemiological studies, quantitative information must be acquired on patterns of drug use to define the intensity of selection that induces the observed change in resistance frequency. Much more thought must be given to defining optimum methods for the use of a number of different drugs, both for the individual patient and for the community, to maximize the effective life expectancy of a drug and minimize the rate of evolution of resistance.

A more encouraging picture emerges for the helminth infections where community-wide use of anthelmintics (often targeted at the child age groups in which the intensity of infection and associated morbidity is greatest) has been very effective in parasite control. To reduce R_0 to less than unity in value, the proportion of the population that must be treated per unit of time (i.e. monthly or yearly) must exceed a critical value, g, where

$$g = 1 - exp[(1 - R_0)/A]/h \qquad (8)$$

Here, A is the life expectancy of the parasite in the human host and h is the efficacy of the drug (Anderson and May 1991). To take a specific example, namely *Ascaris lumbricoides* for R_0 values around 3 and with $A = 1$ year, a drug of 95 percent efficacy would have to be administered to more than 91 percent of the population each year to eradicate the infection (Figure 20). However, if morbidity control is the aim, a much more targeted program of treatment of heavy infection in schoolchildren would suffice. Recent studies show that additional benefits accrue from the treatment of heavy infection, such as improved rates of growth in children,

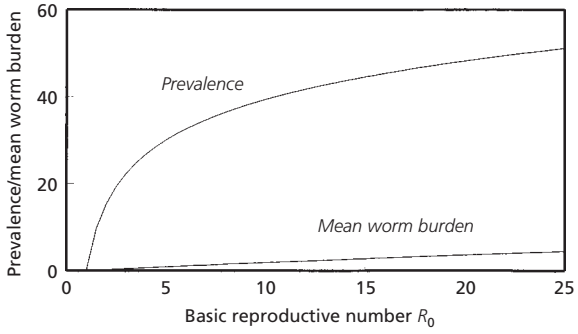

Figure 19 *The relationship between the prevalence and intensity of a macroparasitic infection as a function of the magnitude of transmission success as measured by* R_0. *Below the point* $R_0 = 1$, *the parasite is unable to persist in the host population.*

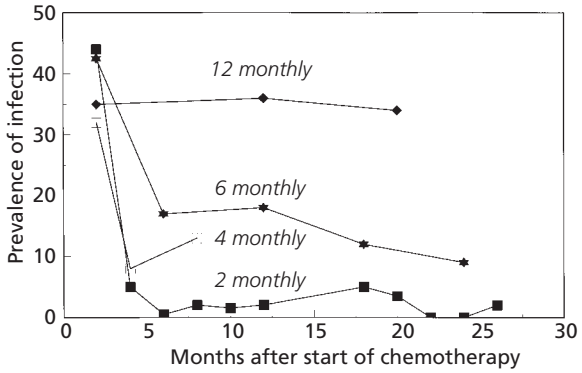

Figure 20 *The influence of different monthly intervals between rounds of mass chemotherapy on the prevalence of* Ascaris lumbricoides *in a study population in Korea (after Seo and Chai 1980)*

improved cognitive function, and a net reduction in transmission in the community as a whole (Nokes and Bundy 1994). A major practical advantage of targeting treatment to children is their accessibility during school attendance. The frequency of treatment following the introduction of control will depend on rates of re-infection as defined by the magnitude of R_0. For long-lived species with limited transmission success, such as the schistosome and filarial worms, intervals of a few to many years may suffice (Butterworth et al. 1991). Conversely, for the short-lived worms such as the intestinal parasites, yearly or more frequent treatment is required (Thein-Hliang et al. 1984).

Long-term control of all parasites in areas of endemic infection will require continual intervention or chemotherapeutic treatment unless the intensity of control is sufficient to eradicate the parasite. For the important infections in tropical regions, eradication is difficult to envisage given limited resources for public health measures. Vaccines are ideally required and their development must remain a research priority in the coming years (see Control of parasites, parasitic infections and parasitic diseases).

The scientific assessment of the effectiveness of a given intervention program in both epidemiological and economic terms, is often poor despite large expenditure in the implementation of a specific program. More rigorous approaches to intervention study design and evaluation are required that meld quantitative epidemiology study pre- and post-intervention, with assessments of cost and benefit. Cost–benefit analyses of different control options must be based on a framework that captures the interaction between the transmission dynamics of the parasite and the intensity of the control measure. This relationship is invariably non-linear and hence intuition alone will not suffice to accurately deduce the potential impact of a given policy. The key problem, however, is often in the design of the intervention program. Detailed statistical analyses are required to determine the correct sample size (whether in units of people or communities) required to detect a defined level of change in the incidence of infection or disease following intervention.

The practical aspects of the control of parasitic diseases are discussed in more detail in Control of parasites, parasitic infections, and parasitic diseases.

CONCLUSIONS

The interdisciplinary character of epidemiological research implies that advances in a wide variety of disciplines will influence our understanding of the processes that control the spread and persistence of infectious agents in human communities in the coming years. These include those in molecular biology, immunology, mathematics, genetics, information handling, storage, and retrieval. Modern desktop computers plus associated software provide a striking illustration of how advances in one field of science can influence progress in epidemiological study. Database construction and handling for a large cohort intervention study is now a simple task, as are comparative studies of sequence data from different patients or pathogen isolates, or detailed statistical analyses seeking associations between host and parasite variables.

However, in parallel with such technical advances, whether in data management or the measurement plus detection of infection or immunity, there is an associated need to broaden the conceptual template on which epidemiological study is based. Until recently, much epidemiological research on infectious agents ignored the very dynamic nature of the interaction between host and parasite populations, both with respect to the dynamics of transmission and evolution. A failure to take account of population biology and evolution may even influence the more practical end of epidemiology, namely, cost–benefit analyses of different control interventions. Such analyses must be based on measures of the impact of control on both transmission success and parasite evolution.

Direct and indirect benefits arise from vaccinating or drug treating individual patients. The direct benefits to the patient are obvious, but the indirect benefits relate to the removal of a host that can potentially pass infection to others. As such, net benefit to the community includes an element related to the reduction in transmission success of the parasite. Drug use may promote the rate of spread of drug resistant parasite strains and hence reduce the period over which a given drug is an effective treatment.

A key problem in all epidemiological studies is the interpretation of heterogeneity in patterns of infection and disease within human communities. It is in this area that recent advances in biological research, particularly at the molecular genetic level, are likely to promote the greatest change in epidemiological research. Genetic diversity in host and pathogen populations is now measurable on the scale required for population-based comparisons and linkage analyses. There seems little doubt that such work will begin to provide answers to such fundamental questions as to why some are predisposed to specific infections and associated disease, while others are not.

Immunology and immunopathology of human parasitic infections

F.E.G. COX AND DEREK WAKELIN

Introduction	1	Responses to parasites may interact with other diseases	30
Immune responses to parasitic infections	2	References	31
Immunity to protozoa	7		
Immunity to helminths	21		

INTRODUCTION

The human immune system is concerned with defense against invading organisms and the removal of malignant cells. The role of the immune system is to deliver an appropriate immune response at the right time and place and it is not surprising, therefore, that different infectious agents should elicit different immune responses. In order to understand the nature of infectious agents, particularly parasites, it is necessary to distinguish between microparasites and macroparasites (see Epidemiology of parasitic infections). Microparasites are small and multiply within their vertebrate host, often inside cells, thus posing an immediate threat unless contained by an appropriate immune response. Viruses, bacteria, and protozoa are microparasites, typically inducing an infection in which the host becomes infected, then experiences a latent period during which the parasites multiply. This is followed by a period of disease and discomfort during which the immune response brings the infection under control and, finally, a gradual recovery and long-term resistance to reinfection. Macroparasites (i.e. helminths) are large and most do not multiply within their vertebrate host and, therefore, do not present an immediate threat after initial infection. However, the host must protect itself from overwhelming infections and reinvasion by infective stages and can only do so by eliciting an appropriate immune response. Immune responses to protozoa (microparasites) and helminths (macroparasites) are therefore very different from one another.

Although protozoa and helminths are very different in terms of the immune responses they elicit, the infections they cause have a great deal in common, usually being long-lasting and, over a period of years, inducing immunopathological changes that may be more dangerous than the infection itself. In short, the parasite invades the host, is recognized as foreign and elicits an apparently appropriate immune response. However, parasites have all evolved mechanisms for evading the immune response and the net result is a situation in which the infection is only partially controlled. As the parasite may not be totally eliminated, the host continues to mount increasingly complex immune responses until the parasite kills the host, the host overcomes the infection or there is an uneasy compromise. During the course of all infections, parasites die or are killed and parasite molecules deposited on host cells may elicit autoimmune responses which, in turn, contribute to the pathology of the infection. Some parasites can avoid eliciting an immune response by mimicking host molecules which, if effective, can be very successful but, if unsuccessful, can initiate an autoimmune reaction. The majority of parasitic infections also elicit powerful inflammatory responses that may alter, render nonfunctional or even destroy host tissues.

Virtually all parasitic infections are long-term and chronic, and it was once thought that there were

no effective, protective immune responses against parasitic infections in humans. It is now clear, however, that some form of immunity is the rule. The evidence for this comes from a number of sources:

- in endemic areas, the majority of people experience clinical immunity to parasitic infections and the prevalence of infection falls with age while immunological parameters increase
- the uneasy compromise that exists after recovery can be broken, for example by immunosuppressive drugs or concomitant infections
- in every experimental model investigated, immunity can be demonstrated and there is no reason why humans should be different.

IMMUNE RESPONSES TO PARASITIC INFECTIONS

The overall immune response

The immune response to any parasite, as with any other infectious agent, begins when the host becomes infected and the parasite is recognized by the cells of the immune system. In order to initiate an immune response, molecules of the parasite must come into contact with the cells of the immune system and, if this does not happen, no immune response will be initiated. Many parasites invade host cells and tissues and thus come into direct contact with the immune system; most intestinal parasites pass through host tissues before reaching their final location. Even for intestinal parasites that do not breach the integrity of gut wall, such as the protozoan flagellate *Giardia duodenalis*, there is the potential for direct antigen uptake across the mucosa and the possibility of evoking an immune response. Once a parasite is recognized as foreign, the next series of events is initiated. The events involved in recognition are complex and much of what we know about them is concerned with peptide antigens. This chapter contains no detailed discussion of carbohydrate antigens although these play an important role in many antiparasite responses. In the simplest situation, the first event that occurs is when parasite peptide antigens are processed by antigen-presenting cells (APC) and transported to the surface of the cell in combination with specific major histocompatibility complex (MHC) molecules. The whole complex, consisting of the MHC molecule and the peptide, is then recognized by antigen receptors on helper T lymphocytes and the immune response proper is initiated. These early steps are known as antigen processing and presentation and these events determine the eventual outcome of the immune response. A number of cell types, particularly macrophages and dendritic cells, can act as APCs. In many parasitic infections, macrophages are involved and, as the antigen on the surface of the APC binds to the receptor on the helper T lymphocyte, the macrophage releases T-cell-activating molecules known as cytokines. In response, the helper T cells produce other cytokines that, in their turn, activate the effector cells of the immune system. The specific target of the immune attack is the antigen that initiated the immune response in the first place but parasites, particularly helminths, are very large targets and the immune system has to recognize a large number of different surface antigens. Not all of these are involved in protection, and some are even able to deflect the immune response away from more vulnerable targets. Much research has been devoted to the identification and characterization of protective antigens in order to try to understand how the immune response to parasites works and how to target vaccines to relevant molecules. Considerable effort has also been put into identifying antigens that are irrelevant to protection, or even counter-protective, or are involved in the evasion of the immune response and the pathology of the disease.

Although the immune responses to parasites are complex, the individual components are relatively simple and there is nothing unique or special about immunity to parasites except for the degree of complexity. In this context, it is convenient to consider the protective immune response against infectious organisms as having three arms:

1. cytotoxic T (Tc) cells
2. activated macrophages
3. antibody.

The Tc cells plus activated macrophages constitute what is conventionally called cell-mediated or antibody-independent immunity, while antibody constitutes humoral or antibody-dependent immunity (Figure 1). The Tc cells engage target cells expressing antigens in combination with class I MHC molecules and bring about their cytotoxic activity by creating pores in the membrane of the target cell, which then ruptures. Tc cells are frequently involved in viral infections but are seldom implicated in parasitic infections. Natural killer (NK) cells constitute a heterogeneous collection of lymphocytes that are neither B nor T cells, are not specific to a particular antigen and do not involve MHC class I molecules. NK cells seem to be able to kill target cells directly by forming pores in the target cell membrane, which ruptures as in Tc cell killing. NK cells are being increasingly implicated in protection against parasitic infections, not necessarily as effector cells but as the sources of important regulatory molecules.

Activated macrophages, macrophages that have been sensitized and triggered by signals such as lipopolysaccharide and interferon-gamma (IFN-γ) are among the most important cells involved in protection against parasites and can kill target cells either intracellularly or extracellularly. If it is small, the target cell can be

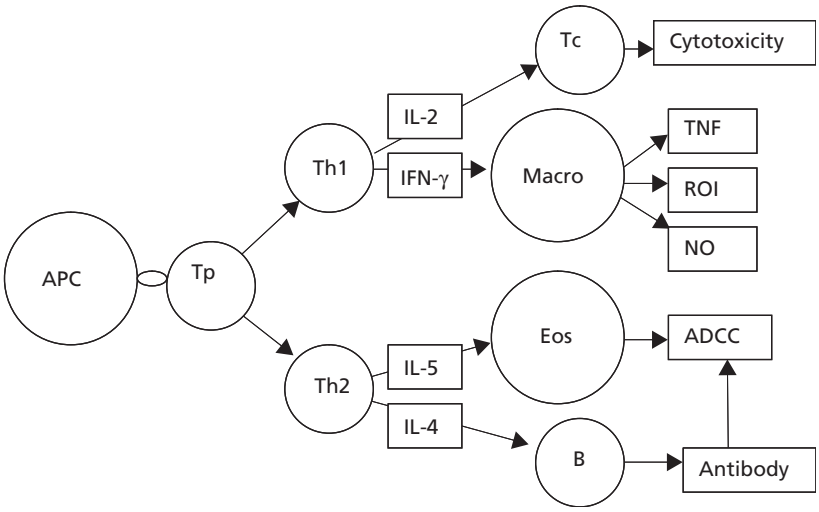

Figure 1 *Diagrammatic representation of the main features of the overall immune response. Antigen is recognized and processed by APCs and presented to precursor T (Tp) cells that carry receptors for the antigen. Depending on the nature of the antigen, and how it is presented, the Tp cells differentiate into Th1 or Th2 cells. Th1 cells produce a number of cytokines including IL-2 and INF-γ. IL-2 activates Tc cells that kill target cells carrying the original antigen in an MHC restricted manner. INF-γ activates resting macrophages (Macro) making them more phagocytic and causing them to release a variety of molecules, including TNF-α, ROI, and NO. ROI and NO are involved in the intracellular killing of ingested parasites or the destruction of parasites in close proximity to the activated macrophage. Th2 cells release a different set of cytokines, including IL-4 and IL-5. IL-4 is involved in B cell differentiation and activation and the release of antibodies specific to the antigen. IL-5 activates eosinophils (Eos). Antibodies may act in cooperation with cells such as eosinophils and macrophages by acting as a bridge bringing the activated cell and the parasite together and facilitating the release of toxic molecules directly onto the surface of the parasite, a process known as ADCC.*

phagocytosed and destroyed in the phagolysosome via a number of pathways including:

- proteolytic enzyme activity
- reactive oxygen intermediates (ROI) (superoxide, hydrogen peroxide and hydroxyl radicals) that destroy the target cell though a process of lipid peroxidation
- nitric oxide (NO) that reacts with the superoxide anion to produce highly toxic peroxynitrite and hydroxyl radicals.

Macrophages also produce tumor necrosis factor-alpha (TNF-α), which has a synergistic effect with NO. These molecules, among other things, interfere with membrane integrity, DNA structure and mitochondrial function and bring about the destruction of, or damage to, target cells. One of the key features of the activation of macrophages is that the various toxic molecules produced are released not only into the phagolysosome but also extracellularly and are thus able to destroy cells in the close vicinity of the activated macrophage. Macrophages are, therefore, able to kill large cells or multicellular organisms, especially if the macrophage is closely bound to the target via, for example, an antibody bridge as described below. These toxic molecules can also damage host cells, and their release in an inappropriate place or in excess is a major cause of immunopathology. TNF-α, for example, is highly toxic and can cause cachexia, hemodynamic dysfunction, neurotoxicity, acidosis, and renal failure; IFN-γ can cause tachycardia, leukopenia, and malaise, and can enhance the effects of TNF-α. The roles of TNF-α, oxygen-derived free radicals, NO, and other molecules in pathogenesis are reviewed by Clark and Cowden (2003).

The most important cells with direct effector functions in immune responses are Tc cells, activated macrophages and B lymphocytes (Figure 1). Each of these cells has its specific role in the immune response and can act concurrently or sequentially, with or without other cells, to bring about the immobilization or destruction of the invading organism. Other cells commonly seen in response to parasitic infections, particularly helminths, include eosinophils (Figure 1). Eosinophilia is a characteristic of a number of helminth infections but the role of these cells in human infections is enigmatic. Much of what we know about the part played by eosinophils in parasitic infections has been derived from histological studies but the elucidation of the role of interleukin (IL)-5, the key eosinophil growth and development factor, has made it possible to examine the role of these cells in more detail. It is now clear that eosinophils do play an important role in resistance to a range of helminth infections in mice, rats, dogs, primates, and humans, and that they are involved in the killing of the larval, but not the adult, stages of these parasites (Meeusen and Balic 2000).

The humoral immune response is concerned with B cell products, i.e. immunoglobulin (Ig) antibodies. The

four major classes, IgA, IgG, IgM, and IgE, occur in different situations and are effective against parasites in different ways although there is some sharing of functions. Antibodies are directly effective against invading organisms in four main ways: neutralization, agglutination, complement activation, and facilitated opsonization. IgA occurs as two subclasses, IgA1 and IgA2, each of which can occur in a monomeric, dimeric or, occasionally, polymeric form. IgA is essentially an antibody found in secretions where it protects the mucous surfaces of the gut, respiratory tract and urinogenital tract; it also occurs in breast milk. Its main functions are the neutralization of bacterial toxins and the inhibition of the invasion of the mucosa, either by agglutinating the infectious agents or blocking attachment to host cells. IgG and IgM are found in the serum and extravascular spaces. IgM, a pentameric immunoglobulin that occurs as a single subclass, is the first antibody produced in response to antigenic stimulation; it is very good at agglutinating microorganisms with repeated epitopes and at activating complement via the classic pathway. IgG occurs as four subclasses (IgG1, IgG2, IgG3, and IgG4), and usually replaces IgM; it is the most common antibody in secondary immune responses. All subclasses can agglutinate microorganisms. IgG1, IgG2, and IgG3 can activate complement, IgG3 being the most effective. IgG1 and IgG4 can pass across the placenta, and IgG1 and IgG3 can bind to macrophages and neutrophils via their Fc portions. IgE has an affinity for mast cells, basophils and eosinophils and, when bound to an antigen, causes cross-linking, resulting in the release of pharmacologically active substances from the cells to which it is bound.

Antibodies seldom work in isolation from other components of the immune system. IgG and IgM fix complement and initiate complement-mediated lysis of the target cell. IgG and IgE bind to macrophages, eosinophils, and mast cells, via the Fc portion, and to the target cell by the Fab portion, and thus facilitate the destruction of the target cell by toxic molecules released by the effector cell, a process known as antibody dependent cell-mediated cytotoxicity (ADCC).

The immune responses evoked during infections with parasites are not unusual and are essentially the same as those involved in immunity to other infectious organisms. What is different is the complexity of the immune response in reaction to diverse antigens expressed by different stages of complicated life cycles often in different locations in the host. This leads to a plethora of antibody-independent and antibody-dependent responses which, over a period of time, can give rise to misdirected immune responses leading to pathological changes instead of protection. For example, the production of TNF-α in malaria is beneficial but in excess is detrimental; in schistosomiasis potentially protective responses lead to the formation of harmful granulomas around nonthreatening eggs deposited in tissues. For these reasons, current interest in immunity to parasites is being concentrated on an understanding of the overall control of the immune response which is brought about by the interactions of the various cytokines involved in a cytokine network.

The cytokine network in parasitic infections

Cytokines are low molecular weight protein mediators that are involved in the growth, differentiation and repair of cells and occupy a central position in the regulation of the immune response. Since their discovery in the 1960s, the study of cytokines has revolutionized understanding of both the control of the immune response and the nature of the pathology associated with diseases caused by infectious organisms. This has become a massive field and is covered in more detail in Cytokines in the Immunology volume of this series and, in the context of infectious diseases, in Kotb and Calandra (2003). The cytokine network acts as a series of signals between the cells of the immune system. Many cytokines are growth or activation factors and without them the immune system could not function. An understanding of the cytokine network has permitted immunologists to unravel the interactions that come into play during an immune response and to consider individual components separately before considering them in the context of the response as a whole. Four main groups of cytokines are involved in the immune response: interleukins, interferons, transforming growth factors, and tumor necrosis factors (Tables 1 and 2). All of these have been intensively studied, particularly the interleukins; about 30 interleukins have been described but there is a considerable degree of overlap in structure and function, particularly concerning the 'over-16s', giving rise to some confusion and concern (Eberl 2002). Among the most important cytokines in the context of immunity to infectious diseases are IL-1–6, 8–10, 12, 13, and 15–18, interferon-alpha (IFN-α), interferon-beta (INF-β) and IFN-γ, TNF-α and tumor necrosis factor-beta (TNF-β). Other cytokines involved, directly or indirectly, in infectious diseases include a group known as chemokines (including IL-8) that are responsible for the induction and migration of subsets of leukocytes. Many cytokines occur in more than one form, e.g. IL-1a and IL-1b, with subtly different functions. Cytokines are produced by many cell types and act on many cell types, including the ones that produce them, in some cases promoting cell activity and in other cases inhibiting it. Thus, there is a network of cytokine activity that can be very difficult to unravel. Nevertheless, it is possible to distinguish two distinct pathways of cytokine activity:

1 the pro-inflammatory pathway (mainly involving IL-1, IL-6, IL-12, IL-15, IL-18, IFN-γ and TNF-α) that leads to cell-mediated immune responses

Table 1 *Interleukins involved in immunity to parasitic infections*

Cytokine	Important source cell(s)	Important target cell(s)	Important action(s)	Role in immunity to parasitic infections
IL-1	Macrophages and virtually all nucleated cells	Macrophages, T cells, B. cells, eosinophils, neutrophils	Lymphocyte activating factor. Stimulation of immune response, increase in production of other cytokines	Involved in all parasitic infections
IL-2	Th1 cells	Th and Tc cells	T cell growth factor. Growth and proliferation of T cells, induction of cytotoxic T cells	Cytotoxic killing of liver stages of *Plasmodium*
IL-3	T cells	Hemopoietic and other cells	Multicolony stimulating factor. Hemopoiesis	Involved in all parasitic infections
IL-4	Th2 cells	B cells, macrophages, mast cells, and other cell types	Proliferation of B cells, direction of immune response to Th2 pole, immunoglobulin switching, inhibition of inflammation	Involved in antibody production in all parasitic infections. Production of IgE. Expulsion of gastro-intestinal nematodes, Inhibition of cell mediated immunity in leishmaniasis
IL-5	T cells, mast cells, eosinophils	Eosinophils, B cells	Eosinophil differentiation factor. Production of eosinophils	Eosinophilia in helminth infections, ADCC killing of helminth larval stages
IL-6	T cells, monocytes, macrophages, and other cell types	B cells, myeloid cells, and other cell types	B cell stimulatory factor. B cell growth and differentiation	
IL-7	Bone marrow cells	Pre-B and pre-T cells	Lymphopoietin. Growth of pre-T and pre-B cells	
IL-8	Monocytes and macrophages	Neutrophils	Neutrophil chemoattraction	
IL-9	Th2 cells	T cells, mast cells	T cell growth factor. Synergizes with IL-4 in antibody production	
IL-10	Th2 cells, monocytes, macrophages	Th1 cells, NK cells, macrophages	Immunoregulation. Enhancement of Th2 responses, inhibition of Th1 cell and macrophage function, inhibition of IL-12, IL-13 and IFN-γ	Inmunity in leishmaniasis. Downregulation of immunity in filariasis
IL-11	Bone marrow cells	Pre-B cells	Promotion of pro-inflammatory cytokines IL-1, IL-6 and NO	
IL-12	Macrophages	T cells, NK cells	NK cell stimulatory factor. Promotion of Th1 responses, inhibition of IL-4 and IL-10	Enhancement of immunity to intracellular protozoa, e.g. *Leishmania*, *Trypanosoma cruzi*, *Toxoplasma*
IL-13	Th2 cells, other T cells, eosinophils, mast cells	B cells, monocytes	Proliferation of B cells, promotion of Th2 differentiation, inhibition of Th1 activities	Expulsion of gastro-intestinal nematodes
IL-14	T cells	B cells	Proliferation of B cells, inhibition of antibody secretion	
IL-15	Monocytes	T cells, NK cells	T cell growth factor. Promotion of Th1 cell activities, enhances cytotoxic activities of T cells and NK cells	
IL-16	T cells	T cells	Chemoattraction	
IL-17	T cells	Macrophages	Initiation of inflammatory responses	
IL-18	Activated macrophages		Induction and enhancement of IFN-γ and NK cell cytotoxicity	Regulation of mast cell and Th2 cytokines in trichinellosis

There is a considerable degree of cross-function among the post-16 cytokines (IL-17 to IL-27) (see Eberl 2002). Most of these cytokines have not been thoroughly investigated in parasitic infections.

Table 2 *Properties of important cytokines in immunity to parasitic infections*

Th1 cytokines	Th2 cytokines	Pro-inflammatory cytokines	Counter-inflammatory cytokines	Cytokines that can lead to pathology[b]
IFN-γ[a]	IL-4[a]	IL-12	IL-4	IL-1
IL-2	IL-5[a]	IL-15	IL-10	IL-6
IL-3	IL-3	IL-18	TGF-β	IL-8
TNF-α	IL-13	IFN-γ		IL-12
TNF-β	IL-6			TNF-α
GM-CSF	IL-10			MIF
	TGF-β			

a) These are the most important cytokines.
b) For example, increased vascular permeability, tissue damage, circulatory collapse, multi-organ failure etc.

2 a pathway (involving IL-3, IL-4, IL-5 and IL-13) that leads to the activation of the humoral immune response, the production of antibodies and the activation of inflammatory cells.

These distinctions are not absolute and some cytokines can have contrasting functions, for example IL-6 is a pro-inflammatory cytokine that can also indirectly damp down such responses through its ability to control the production of acute phase proteins. In all infections there are well-regulated pathways of cytokine activity that lead to protection but these are nearly always accompanied by counter-protective pathways that damp down potentially damaging side-effects (Figure 2). Many cell-mediated immune responses, for example, are characterized by the production of dangerous molecules such as TNF-α and NO that can cause pathology but are modulated by other cytokines such as IL-4, IL-10, and IL-13.

From the moment an immunologically intact host is infected with a parasite or any other infectious agent, the host begins to mount an appropriate protective immune response. The key cells are the so-called T helper (Th) lymphocytes characterized by the possession of a CD4 surface marker. At first, these are uncommitted but gradually differentiate into Th1 and Th2 cells, each characterized by the cytokines they produce, until eventually they become fully differentiated; when this happens, they are mutually exclusive. The Th1 cells produce T1 cytokines that drive the immune response towards antibody-independent immune responses, in particular IL-2 that drives the immune response towards the production of CD8 Tc cells and IFN-γ that drives the response towards the activation of macrophages. Th2 cells, on the other hand, produce IL-4, IL-5, IL-10, and IL-13 that lead to the activation of B cells, and the subsequent production of antibody, and to the proliferation and differentiation of eosinophils. A third subset of Th cells, Th3 or T-regulatory (Tr) cells produce cytokines such as IL-10 and transforming growth factor-beta (TGF-β) that down-regulate the activities of other Th cells and, therefore depress or even suppress the immune response. In short, the Th1 responses represent the cell-mediated arm of the immune response and the Th2 responses represent the humoral arm. Tc cells are ideally suited for the destruction of virus-infected cells, IFN-γ-activated macrophages are involved in the killing of intracellular pathogens and the antibody produced by B cells is most effective against extracellular pathogens such as helminth worms. The role of Th1 and Th2 cells in a number of infectious diseases is well discussed in the various contributions in Romagnani (1996) and Kotb and Calandra (2003). Parasites are no different from other pathogens in that they inevitably induce some kind of immune response except that Tc cells are less involved in parasitic infections than in viral infections. In general, it is widely accepted that protective Th1 responses predominate in infections caused by intracellular protozoa whereas Th2 responses are more important in immunity to extracellular helminth infections. With reference to specific examples, toxoplasmosis (like tuberculosis) is highly polarized towards the Th1 pole, leishmaniasis (and leprosy) tend towards the Th1 pole, malaria tends towards the Th2 pole and helminth

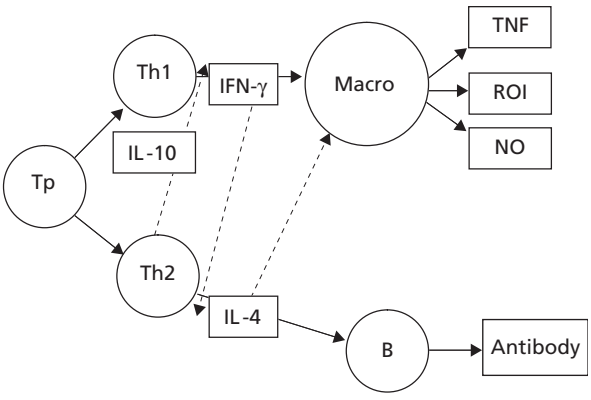

Figure 2 *Diagrammatic representation of the cytokine cross-regulation of the immune response. IFN-γ, as well as having a positive role in the activation of macrophages (Th1 response) has a negative effect on Th2 responses. Similarly, the Th2 cell products IL-4 and IL-10 inhibit Th1 responses. Positive pathways are here indicated by solid lines and negative pathways by broken lines.*

infections are polarized to the Th2 pole (Garraud et al. 2003). In addition, the mutual exclusivity mentioned above frequently results in extreme polarization in which one arm of the immune response is protective and the other counter-protective. However, these are generalizations and the details of each individual immune response can differ from time to time or from stage to stage of an infection. It is also important to bear in mind that the Th1/Th2 paradigm is not a rigid set of rules and that there may be switches in the patterns of Th1 and Th2 cytokines during the course of an infection (Allen and Maizels 1997).

Th cell subsets and the cytokine network were originally identified and defined in mice (Mossman and Coffman 1989) but virtually every component has since been shown to apply to humans as well (Romagnani 1991); parasitic infections provided the first evidence for human Th cell dichotomy. Currently, extrapolations are made from mouse to human and are tested before any definite assumptions are made.

The polarization of T cells towards cell-mediated or antibody-mediated responses does not depend entirely on the infectious agent involved but can be modulated by pre-existing factors including the cytokines present locally. For example, the presence of IL-12 or IFN-γ drives the immune response towards the Th1 pole whereas IL-4 drives it towards the Th2 pole (Ma et al. 1997). Initial or subsequent polarization involves the interaction of a number of regulatory cytokines some of which act as growth and differentiation factors. What is important here is that these cytokines, and also effector molecules, act nonspecifically. It is, therefore, possible for one infectious agent to be caught up in the cytokine network generated in response to another acquired previously, concurrently or subsequently (see Cox 2001).

Another important factor in determining the outcome of an infection is whether or not the established infection is inducing a Th1 or a Th2 response. The Th1 immunological milieu involves a number of molecules and the cells that produce them, in particular, NK cells, IL-12, and IFN-γ. The initiation of a new immune response in such a situation is gradually forced towards the Th1 pole and, if the superimposed agent is controlled by Th2 responses, it is at an advantage in such a situation. The converse applies if IL-4 predominates in the immunological milieu at the time of the second infection.

By the beginning of the 1990s, a general pattern emerged in which it appeared that, in the majority of protozoal infections in experimental models, Th1 cells were protective and Th2 cells were counter-protective, whereas in helminth infections the opposite was the case, Th2 cells were protective and Th1 cells counter-protective (Cox and Liew 1992). It is now clear that the interplay between cytokines in the immune response to parasites is not as simple as it once seemed to be and can vary over the duration of the infection, at different sites in the host, between different species or strains of hosts and between different strains of parasite (Allen and Maizels 1997). Nevertheless, the Th1/Th2 dichotomy is a useful concept when attempting to unravel the complex immune responses that occur in parasitic infections; this can be illustrated by reference to NO, a reactive gas with many functions that has assumed a central role in our understanding of the immunology and immunopathology of parasitic infections. Its role in cell signaling has been known for a long time but it is only in the past decade that its role in immunity to infection has been understood (Clark and Rockett 1996). There are two important isoforms of NO: constitutive and inducible. Constitutive NO is found in a variety of cells. Inducible NO is produced by macrophages under the control of the enzyme inducible nitric oxide synthase (iNOS). NO is a powerful antimicrobial compound and is capable of killing a range of organisms including bacteria, protozoa, and helminth worms. It acts on iron–sulfur clusters in macromolecules and represses DNA synthesis and iron-containing enzymes, including those involved in respiration. Nitric oxide synthase is up-regulated by IFN-γ and TNF-α and is down-regulated by IL-4, IL-5, and IL-10. NO is, therefore, a key molecule in the immune response to parasitic infections and its production and activity are favored by Th1 responses. However, NO is also potentially dangerous and is inhibited by Th2 responses (James 1995).

It is important to understand the cytokine system in parasitic infections because of the complexity of the immune responses involved when coping with highly evolved and antigenically diverse pathogens, and in order to interpret events leading to protection on one hand and pathology on the other. Interpretations from only a few years ago of the immune response to parasites now seem very simplistic and new discoveries have called for a reinterpretation of many of the facts observed. On the other hand, new discoveries have enabled us to understand much more clearly many of the phenomena previously observed. In the remainder of this chapter, these points are illustrated by reference to the most important parasitic infections in terms of human parasitic diseases.

IMMUNITY TO PROTOZOA

Characteristics of protozoa in relation to the immune response

Unlike most viral and bacterial infections, protozoal infections tend to be chronic and to be associated with inappropriate immune responses, immunodepression to superimposed infections and immunopathological damage. This pattern has parallels with the patterns found in mycobacterial infections, leprosy, and

tuberculosis, in which most individuals usually develop some immunity to the clinical disease while never actually eliminating the infection altogether. The immune response patterns to these infections are also seen in bacterial infections, such as listeriosis, and in sepsis. Leprosy, tuberculosis, and many protozoal infections present similar problems and the study of protozoa is now providing important clues as to what is happening in other infections (see Kotb and Calandra 2003). Our increasing knowledge of immune responses to protozoa is also beginning to explain the immunopathology associated with such infections because long-term chronic infections continually stimulate the immune system, which responds inappropriately and can eventually begin to attack the body itself. It is now clear that an understanding of the roles of cytokines is central to understanding the protective immune response, immunopathology and the possibility of developing vaccines. In this context, the use of inbred strains of laboratory mice has been invaluable and the ease with which genes can be deleted or inserted makes it possible to dissect these immune responses in great detail, to identify the roles of particular cytokines, and to extrapolate from mice to humans.

Infections with *Leishmania* species in inbred strains of mice have become the paradigms for studies on T cell subsets and the cytokine network as a whole. Early investigations using *L. major* in mice revealed that there is antagonism between the products of Th1 cells (IFN-γ) and Th2 cells (IL-4 and IL-10), the former leading to protection and the latter to counter-protection. It was later shown that the effector molecule involved in parasite killing was NO. These early observations subsequently proved to be very simplistic but provided a basis for more detailed investigations of leishmaniasis and of other parasitic protozoa. *Toxoplasma gondii* is also a parasite of macrophages and, like *Leishmania*, is controlled by IFN-γ-activated macrophages and the production of NO, TNF-α synergizes with IFN-γ in this killing. Malaria is a complex infection and immunity involves both Th1 and Th2 responses; parasite killing involves both antibodies and NO, which is also responsible for much of the pathology associated with severe malaria. Studies on cytokines have now extended to all the protozoa that infect humans, and research in this area is probably one of the most intense and productive areas of parasite immunology. It is probably true to say that in most, if not all, infections either the Th1 or the Th2 response is protective whereas the other is counter-protective and can lead to pathological changes or switching off the protective immune response.

Protozoa are microparasites that multiply within their vertebrate hosts by dividing at a genetically determined rate; thus, no matter how small the initial infective dose, the infection will eventually overwhelm the host unless it is controlled. The only ways in which this rate of multiplication can be curtailed are exhaustion of the cells available for infection or intervention of an immune response. In protozoal infections, some kind of acquired immunity is the rule and the main reason why this does not eliminate the infection is because all protozoan parasites have evolved ways of evading the consequences of the immune responses that they have evoked (Zambrano-Villa et al. 2002). Protozoal infections, therefore, tend to be long and chronic. The general pattern is, typically, a latent period during which few or no parasites can be detected, a phase of logarithmic increase, a crisis during which the infection is brought under control, and a rapid or gradual decline leading to a chronic infection with the possibility of subsequent recrudescences and long-term immunopathological damage.

All protozoal infections are accompanied by a number of immunological changes including the production of specific antibodies, usually IgM followed by IgG, and cell-mediated responses that can be measured in various ways. It is often not appreciated that many of these immunological responses have little or nothing to do with protection. All protozoa are antigenically complex and are, therefore, recognized as foreign so a variety of immune responses is inevitably initiated. These responses are often either due to irrelevant antigens or to relevant antigens that the parasite is able to use as part of its repertoire of immune evasion techniques. For example, antibodies to the dominant antigen of the malaria sporozoite deflect the immune response away from more vulnerable targets; in leishmaniasis, antibodies merely represent the stimulation of a counter-protective Th2 response.

In summary, protozoal infections are accompanied by changes in immunological parameters that, in some cases, mirror recovery but do not necessarily represent a protective mechanism. Unfortunately, a vast amount of the literature on the immunology of protozoal infections is devoted to these 'will-o'-the-wisps' and this has tended to obscure and confuse valid and relevant observations.

The importance of protective immune responses to protozoa has been highlighted by the consequences of co-infections with human immunodeficieny virus (HIV). Protozoal infections such as cryptosporidiosis, cyclosporiasis, and also microsporidiosis, once thought to be rare and harmless, are now recognized as concomitants of acquired immune deficiency syndrome (AIDS) with major pathological potential (see Intestinal coccidia: cryptosporidiosis, isosporiasis, cyclosporiasis, and 25, Microsporidiosis). HIV is known to adversely affect the immune response to a number of other protozoal infections including leishmaniasis, toxoplasmosis, and Chagas disease (Ambroise-Thomas 2001), but does not seem to affect the outcome of malaria or African trypanosomiasis. The occurrence of such protozoal infections in immunosuppressed and immunocompromised patients has become an important aspect in

the management of AIDS patients. Thus, in many parts of the world, an understanding of the immune response to parasitic protozoa has taken on a new significance.

Immunity to intestinal protozoa

The gastrointestinal tract serves as a habitat for a number of organisms including viruses, bacteria, protozoa and helminth worms. In normal, healthy individuals the mucus layer of the gastrointestinal tract passively protects the underlying cells from invasion. In addition, there is a specialized mucosal immune system consisting of mucosa-associated lymphoid tissue (MALT), intra-epithelial lymphocytes, macrophages and T and B lymphocytes in the lamina propria together with secreted noncomplement fixing immunoglobulin, IgA. Singly or together, these elements provide the first line of defense against invading organisms that gain entry to the body via the alimentary tract. Thus, the immunology of the gut can be considered as a discrete component of the overall immune system. Once an organism has broached the intestinal defenses, it effectively no longer occupies the gastrointestinal compartment of the body and becomes subject to attack by other components of the immune system. It is necessary to consider immunity to intestinal protozoa against this background. In this context, it is important to note that many experimental studies have involved the administration of parasite antigens by routes other than the intestinal one; thus, the immune responses generated have not necessarily been appropriate. The literature on immune responses to intestinal protozoa has been confused by results of such experiments and many of the conclusions drawn probably have little validity. This section, therefore, stresses what is known about immunity to intestinal protozoa in humans and underemphasizes the contributions made by animal and in vitro studies. The comprehensive reviews available will be cited.

INTESTINAL AMEBAE

Entamoeba histolytica is the only ameba of importance about which anything concerning the immunology is known. There is some controversy as to whether or not all strains of this parasite are pathogenic (see Amebiasis: *Entamoeba histolytica* infections) but, in thecontext of this chapter it is assumed that they are not. Most strains of *E. histolytica* are nonpathogenic and liveas harmless commensals in the large intestine where they do not appear to elicit any immune response. Pathogenic forms can invade the mucosa and submucosa, causing deep ulcers, and may be carried in the bloodstream to the liver, where they cause large abscesses. Immune responses, indicated by the production of specific antibodies, are elicited at various stages after invasion but there is no real evidence that recovery from infection induces any protection against subsequent infections nor, at the population level, is there any age-dependent diminution in prevalence that can be ascribed to the acquisition of immunity. In patients with invasive amebiasis, there is a transient secretory immune response followed by the production of serum antibodies (Pérez-Montfort and Kretschmer 1990). The secretory immunoglobulin, IgA, is probably the most important antibody in the gut. Mucosal IgA antibodies directed against a galactose lectin correlate with the development of resistance in children (Haque et al. 2002) but this resistance is very short-lived (Stanley 2001). There is no correlation between serum antibodies, predominantly IgG, and the severity of the infection or recovery. It is not clear whether the apparent absence of acquired immunity is due to some defect in the immune system or to the fact that the amebae have evolved ways of evading the humoral immune response. Evasive mechanisms include the capacity to degrade IgG and secretory IgA, to resist complement lysis and to redistribute and shed surface antigens (see Zambrano-Villa et al. 2002). In some but not all individuals with invasive amebiasis, there is a transient cell-mediated immune response as detected by skin tests, but it is not at all clear what role cellular immune responses play. The epithelial cells that the amebae invade can produce a variety of chemokines and cytokines as well as mediators such as NO so it is possible that cell-mediated immune mechanisms could play some role in protection. Cell-mediated responses are depressed during *E. histolytica* infections; in vitro studies show that amebae can lyse target cells, including those of the immune system, by inserting ion channels called amebapores into their membranes. *E. histolytica* can also promote the production of the Th1 cytokines, IL-4 and IL-10, and block the production of IL-18 (Que et al. 2003), two mechanisms known to inhibit cell-mediated immune responses. In conclusion, there is some evidence that humans mount an effective immune response against *E. histolytica*, that this involves secretory mucosal IgA, and that any immunity is transient. However, the fact that recurrences of amebic ulcers are rare could suggest that there is some kind of longer-lasting immune response; this warrants some attention. Various aspects of amebiasis, including immunology, are reviewed by Stanley (2001), Petri (2002), and Haque et al. (2002) (see also Amebiasis: *Entamoeba histolytica* infections).

There have been a number of attempts to develop vaccines against *E. histolytica* including DNA vaccines incorporating genes for a galactose lectin; this vaccine elicits a cell-mediated immune response (Gaucher and Chadee 2002). The possibilities and problems associated with developing vaccines against amebiasis are discussed by Miller-Sims and Petri (2002).

INTESTINAL FLAGELLATES

Giardia duodenalis has been long considered to be a harmless commensal of the small intestine but increasing evidence that it can cause malabsorption and severe diarrhea has stimulated interest in immune responses to this parasite (see Giardiasis). A number of experimental studies with *G. muris* in mice clearly demonstrate that there is acquired immunity and protection against subsequent challenge and immunity is genetically controlled. In mice, the key molecule is secretory mucosal IgA. Mice can also be infected with the human parasite *G. duodenalis* and, in this model, there is an IL-4-dependent, Th2-type protective response involving the production of IgA (Bienz et al. 2003; Zhou et al. 2003). In humans, the evidence for acquired immunity is more circumstantial but comes from a number of sources. There is usually spontaneous clearance and resistance to reinfection; those living in endemic areas are less affected than visitors, young children are more affected than older ones or adults, and immunodepressed individuals tend to experience long chronic infections (reviewed by Janoff and Smith 1990; Nash 1994; Kulda and Nohynkova 1995; Faubert 1996; see also Giardiasis). All the available evidence suggests that the effector mechanism or mechanisms involve secretory IgA but the case is by no means proven. IgA is the most characteristic *Giardia*-specific antibody in patients with acute giardiasis and individuals with hypogammaglobulemia tend to experience chronic infections, but there is little direct evidence of any IgA antiparasitic effects. On the other hand, specific antibodies are found in human milk and saliva; breast-fed infants in endemic areas seem to acquire some degree of protection (Walterspiel et al. 1994). Other antibodies may also be involved, for example, current infections are accompanied by high levels of specific IgM but this is quickly replaced by IgA in acute infections and after re-exposure. Overall, it seems that immunity to giardiasis is similar to immunity to a number of bacterial infections in which secretory IgA in breast milk protects the new born infant until it can produce its own antibodies. IgA, which cannot fix complement, presumably adversely affects the parasites indirectly by preventing attachment to the villi. *G. duodenalis* can undergo antigenic variation although the actual mechanism is not understood (Nash 1997). The variant specific surface antigens constitute a family of unusual proteins and it is more likely that they have a biological role, possibly protecting them against intestinal proteases, than any immune evasive mechanism (Nash 2002). There have been reports of giardiasis in AIDS patients, but *Giardia* is not considered to be a major concomitant of HIV infections (Janoff et al. 1988). There is no vaccine against giardiasis and most observers do not believe that one is necessary. The immunoprophylaxis and immunotherapy of giardiasis is reviewed by Olson et al. (2002).

Although the human intestine is parasitized by a number of other flagellates including *Chilomastix mesnili*, *Dientamoeba fragilis*, and *Trichomonas hominis*, these are not normally regarded as important pathogens and virtually nothing is known about any immunological responses to them.

INTESTINAL COCCIDIANS

Little is known about the immune responses of humans to any of the three intestinal coccidians, *Cryptosporidium parvum*, *Isospora belli*, or *Cyclospora cayetanensis*. Cryptosporidiosis is the only important disease caused by any of these parasites and has only been recognized as such during the last 20 years (reviewed by Martins and Guerrant, 1995; see also Intestinal coccidia: cryptosporidiosis, isosporiasis, cyclosporiasis). In healthy individuals, the infection is an unpleasant but self-limiting one, lasting less than a month and characterized by mild to severe watery diarrhea. In AIDS patients, the infections are more persistent, the symptoms much more severe and death may result (Adal et al. 1995). This suggests that normally there is immune involvement and specific antibodies have been detected in the serum of infected individuals; characteristically, IgM is produced first and then replaced by IgG, levels of which begin to decline after about a year. Nothing is known about the possible mechanisms or relevance of these immunological responses.

INTESTINAL CILIATES

Balantidium coli, the only intestinal ciliate of humans, is comparatively rare. Nothing is known about the immune responses to this ciliate and, by analogy with *Entamoeba histolytica*, it is unlikely that there is any reaction unless the mucosa and submucosa are invaded.

Immunity to protozoa inhabiting the urinogenital tract

The only protozoan that inhabits the human urinogenital tract is *Trichomonas vaginalis*, which parasitizes both men and women. The nature of the infection and the disease caused in men is poorly documented, but vaginitis caused by this parasite is an important sexually transmitted disease in women, in whom it persists for long periods unless treated (reviewed by Honigberg and Burgess 1994; see also *Trichomonas* infections). There are no really appropriate animal models of human trichomoniasis and, although experimental infections in guinea pigs and mice have provided some information (e.g. complement-dependent and

complement-independent killing in animals given intraperitoneal, intradermal or subcutaneous injections), little that is really relevant can be derived from these observations (Ackers 1989). Similarly, observations on *T. foetus* in cattle have been largely irrelevant to human trichomoniasis. In humans, secretory IgA antibodies to *T. vaginalis* have been detected in vaginal secretions. Antibodies produced in response to infection diminish with time and do not appear to confer any protection against reinfection. Epidemiological evidence, derived from many studies in sexually transmitted disease clinics, suggests that infections with *T. vaginalis* tend to be persistent, that reinfection frequently occurs after cure and that the prevalence of the infection does not plateau or fall off in the older age groups. All this suggests that there is little or no acquired immunity and that specific immune responses play an insignificant role in limiting this infection. The reasons why there appears to be no immunity to *T. vaginalis* are not clear, although it has been suggested that this parasite has considerable antigenic diversity; whether or not it can also undergo antigenic variation is an open question (Alderete 1983).

Immunity to macrophage-inhabiting protozoa

INTRODUCTION

Three groups of parasitic protozoa inhabit macrophages at some stage during their life cycles: *Leishmania* spp., *Toxoplasma gondii*, and *Trypanosoma cruzi*. Each has evolved its own way of evading the destructive mechanisms of the macrophage: leishmanias survive in the fused phagolysosome; *T. gondii* prevents phagosome–lysolysosome fusion and *T. cruzi* escapes from the phagosome into the macrophage cytoplasm. In addition, all these parasites also possess enzymes that counteract the various toxic molecules present in the phagolysosome. Because of their ability to avoid destruction by macrophages, they all escape attack by one of the main arms of the immune system and this enables them to give rise to long chronic infections. On the other hand, none of these parasites is able to survive in IFN-γ activated macrophages, thus they live on a knife edge by inhabiting cells that can sustain them but which also have the capacity to destroy them. *Leishmania* spp. are totally dependent on macrophages whereas *T. gondii* and *T. cruzi* are also able to parasitize other cell types. This section deals with immunity to *Leishmania* spp. and *Toxoplasma gondii*. *T. cruzi* is discussed later under Immunity to tissue-inhabiting protozoa.

Leishmania spp.

About 20 species of *Leishmania* are known to infect humans in the New and Old Worlds and the number is gradually increasing. Leishmaniasis can be conveniently classified into three forms, cutaneous, mucocutaneous, and visceral, but these categories are not absolute (see Old World leishmaniasis and 17, New World leishmaniasis). As these parasites are very common and as the majority of those infected (particularly with the cutaneous forms) do recover, albeit slowly, the immunology has been intensively studied, mainly with the ultimate aim of producing a vaccine. *L. major*, the causative agent of Old World cutaneous leishmaniasis, and *L. donovani*, the causative agent of visceral leishmaniasis, have been the most studied species, mainly because of the ease with which they can be maintained in genetically characterized laboratory mice. In particular, certain strains of mice (e.g. C57Bl) are relatively resistant to infection and develop small self-healing cutaneous lesions whereas others (e.g. BALB/c) are more susceptible and develop overwhelming visceralizing infections (reviewed by Liew 1990; Alexander and Russell 1992; Liew and O'Donnell 1993; Bogdan and Röllinghoff 1998, 1999; Tacchini-Cottier et al. 2003). Developments in molecular biology, particularly the use of knock-out mice, have made it possible to dissect the immune response to *L. major* in considerable detail and the *L. major*–mouse model has become a paradigm for all leishmanial infections. *L. major* infections in resistant mice tend to resemble most *L. major* infections in humans in the New World and *L. major* infections in susceptible mice resemble the condition known as diffuse cutaneous leishmaniasis (DCL). Models of visceral leishmaniasis, caused by *L. donovani*, and infections with the New World species have not been so extensively investigated but, in general, extrapolations from mice and hamsters to the human situation have tended to confirm the universal nature of the immune response involved. Immunity to leishmaniasis is cell-mediated and involves Th1 cytokines. Leishmanial parasites survive and multiply within normal resting macrophages but are killed by activated macrophages through a mechanism involving NO. NK cells and the cytokines IL-12, IL-18, TNF-α, and TNF inducers play major roles in this process by up-regulating the IFN-γ-induced NO killing. In essence, the protective immune response in leishmaniasis is a classical Th1-type cell-mediated response. However, this protective response is counteracted by an equally effective Th2 response involving IL-4, IL-10, IL-13, and TGF-β. IL-4 and IL-13 counteract the macrophage-activating effects of IFN-γ, IL-10 down-regulates macrophage activity, and TGF-β blocks IFN-γ-activated macrophage activity. The net result is that NO production is inhibited and parasite killing reduced. Resistant strains of mice tend to have high levels of IFN-γ and low levels of IL-4 and IL-10, whereas the opposite is the case in susceptible strains. The overall control of the immune response, therefore, depends on the activation of one of two subsets of T lymphocytes: activation of Th1 cells leads to the production of IFN-γ and protection whereas activation of Th2 cells produces IL-4 and IL-10 and is

counter-protective (see Reiner and Locksley 1995; Scott 1996). It is now clear, however, that this is not the whole story; the actual control of immunity to leishmaniasis is much more complicated and the role of IL-12 and the interplay between IL-12 and IL-4 are crucial to the outcome of the infection (Scott and Farrell 1998). It is also important to note that in mice infected with *L. donovani*, the dichotomy between Th1 and Th2 responses is not nearly so clear cut (Kaye 1995) possibly indicating important differences in antigen processing and presentation in the skin and in the viscera (Moll 1993; Solbach and Laskay 1995, 2000; Ritter and Korner 2002). It is also significant that although IL-12 enhances the production of chemokines important in protection against *L. major* infections (Zalph and Scott 2003), in *L. mexicana* infections in mice there is an alternative pathway leading to the production of IFN-γ that is independent of IL-12 (Buxbaum et al. 2002). Overall, it is now clear that although the general patterns of immunity are similar, there are significant differences between the actual mechanisms involved with different species of *Leishmania* and to some extent this may account for differences in the pathologies associated with different species.

Although the distinctions between the Th1 and Th2 subsets are not so clear cut as in mice, this pattern is also true for human leishmaniasis including visceral leishmaniasis (Kemp et al. 1996). In patients with fulminating *L. donovani* infections, IL-4 and IL-10 levels tend to be high and IFN-γ levels low; in cutaneous infections (in which recovery is normally the rule) IFN-γ levels are high, and in chronic mucocutaneous infections IL-4 levels are high. All these facts are in accordance with well-established clinical observations such as the development of strong delayed type hypersensitivity (DTH) indicating macrophage activation, which correlates with recovery from cutaneous leishmaniasis; diffuse cutaneous leishmaniasis is characterized by the absence of DTH; and high levels of nonprotective IgM and IgG antibodies (resulting from Th2 cell activity) are seen in visceral leishmaniasis (see Blackwell 1993). In localized mucocutaneous leishmaniasis, Th1 cytokines predominate whereas in the more destructive forms there is a mixture of Th1 and Th2 responses, although the Th2 cytokine, IL-4, tends to predominate in accordance with the well-established paradigm (Pirmez et al. 1993). In humans, the nature of the immune response is also determined by numerous extraneous factors such as the species or strain of parasite involved, the genetic makeup of the host or host population, the number of bites by infected sandflies, and the number of parasites injected.

There have been a number of experimental vaccines developed against leishmaniasis and there have been some encouraging results in humans (Greenblatt 1988; Convit et al. 1989; Modabber 1995; Handman 1997). Vaccines that have been used or considered for use include attenuated strains, killed parasites, parasite extracts or metabolic products and, more recently, DNA vaccines. The use of relatively crude vaccines is still going on. Vaccines based on autoclaved *L. major* and *L. infantum* plus bacille Calmette–Guérin (BCG) have been successful in protecting dogs against these infections (Mohebali et al. 1999) and multiple injections of autoclaved *L. major*, with or without BCG, elicit immune responses that suggest that BCG could boost the immune response in humans (Alimohammadian et al. 2002). The possibility of using such vaccines against *L. donovani* in humans is discussed by Dube and Srivastava (2002). Two kinds of vaccine, one using genetically attenuated *L. major* and the other using autoclaved parasites, produced encouraging results in monkeys; both protocols are safe in humans but require further improvement before vaccine development can be contemplated (Amaral et al. 2002). A better characterized vaccine using five *L. infantum* antigenic determinants plus BCG gave 90 percent protection in dogs (Molano et al. 2003). These promising results have encouraged others to develop more advanced vaccines such as recombinant (de Carvalho et al., 2003) or DNA vaccines in mice infected with *L. major* (López-Fuertes et al. 2002; Méndez et al. 2002) or *L. donovani* (Sukumaran et al. 2003). Currently there are many leads but no effective and safe commercially available vaccines against leishmaniasis.

Toxoplasma gondii

Toxoplasma gondii is a common parasite of cats, which can be transmitted to virtually all warm-blooded animals (Dubey and Beattie 1988; see also Toxoplasmosis). The parasites infect macrophages in which they survive by preventing phagosome–lysosome fusion; they undergo rapid division to form merozoites known as tachyzoites. The tachyzoites escape from the host cell and invade new cells. After a short time, this rapid division slows down and the parasites transform into slowly dividing bradyzoites, which remain dormant in cysts in various tissues, including the brain, where they may die and become calcified. If the infected individual is subsequently immunocompromised in some way, the dormant parasites in the cysts may become activated and give rise to a fulminating infection. In humans, most infections are benign or inapparent but if the parasite crosses the placenta it can seriously damage the fetus. *Toxoplasma gondii* infections are also now becoming serious concomitants of AIDS (Ambroise-Thomas and Pelloux 1993). The most obvious features of human *T. gondii* infections are that individuals acquire the infection relatively early in life and after recovering from it are immune to reinfection. Acute infections are characterized by specific IgM and chronic or recovered infections are characterized by high levels of specific IgG. *T. gondii* infections in all mammals except cats seem to be very similar so there

is no major problem in extrapolating from studies in laboratory animals to humans. Much of what is known about immunity to toxoplasmosis has been derived from studies in mice mainly because of the ease with which various components of the immune response can be manipulated in these animals (Gazzinelli et al. 1993; Alexander and Hunter 1998; Wille and Hunter 2003). There have also been numerous parallel studies using sheep, as toxoplasmosis is a serious veterinary problem associated with abortions. The immune response varies throughout the infections. First, there is the innate immune response during which the infected resting macrophages produce small amounts of IL-1, IL-12, IL-18 and TNF-α. These cytokines stimulate NK cells to produce IFN-γ which activates the infected macrophage and brings about NO-mediated parasite killing. This innate immunity is, however, of limited efficacy and duration and the infection then moves into its acute phase during which the infected macrophages produce IL-12 that stimulates both CD4 and CD8 lymphocytes to produce IFN-γ which, in turn, stimulates the production of NO in the infected cell and subsequent parasite killing. During the chronic phase of the infection, CD8 cells seem to be the main source of IFN-γ and the infection is tolerated at a low level until the parasites die and become calcified. If, however, an individual is immunocompromised in some way during the chronic phase of the infection, there is a rapid and acute recrudescence of the parasitemia, which can be fatal. In addition to the Th1-type immune response, there is evidence of some Th2-type activity during which tachyzoites are coated with antibody and are either prevented from invading host macrophages or are unable to prevent phagosome–lysosome fusion if invasion is successful. As pointed out above, antibody levels are indicative of acute or chronic infections.

The key molecule in immunity to toxoplasmosis is NO, which kills the target cell by interfering with DNA and metabolic pathways. NO is a very toxic molecule and over-production can cause pathological damage to host cells and tissues and can also cause immunosuppression. In toxoplasmosis, the pathology is manifested in toxoplasmic encephalitis and retinopathies. The host, however, is able to moderate these adverse effects by producing IL-6, IL-10, and TGF-β, which inhibit the activity of IFN-γ and hence the production of NO. However, TGF-β also promotes the replication of the parasite (Nagineni et al. 2002). The roles of IL-6 and IL-10 are equivocal in that IL-6 actually promotes parasite proliferation which, with IL-10, can contribute to toxoplasmic encephalitis. IFN-γ plays a central role in toxoplasmosis as it not only induces microbicidal activity but also promotes cyst formation and prevents cyst rupture. There are numerous possible sources of IFN-γ, both T cell and non-T cell, and at least five mechanisms whereby IFN-γ-activated macrophages can affect the parasite – including the production of NO and ROI and limiting the supply of iron to the parasite (Suzuki 2002). The immune responses to *T. gondii* are very complex; immunity to infection and the deleterious effects of inflammation are two sides of the same coin and it is essential for the host to maintain a balance between the various cytokines. In order to understand the mechanisms involved in the control of the cytokine network, recent research has moved away from the cytokines themselves to the signaling pathways and the ways in which *T. gondii* can disrupt macrophage function. *T. gondii* induces the activation of two transcription factors, the signal transduction activator of transcription (STAT)-1 and nuclear factor kappa B (NFκB), but blocks their translocation so that the macrophage cannot then produce IL-12 or TNF-α (Denkers et al. 2003).

It is not easy to make direct extrapolations from mice to humans but the available evidence suggests that the mechanisms of immunity in humans are similar to those in mice; for example, IFN-γ inhibits replication of the tachyzoites in macrophages from infected AIDS patients (Delemarre et al. 1994). In vitro studies using human cells have also confirmed murine studies. Using *T. gondii* - infected human myelomonocytic cells, Belloni et al. (2003) have confirmed that TNF-α and IFN-γ act synergistically and have also shown that TNF-α production is inhibited by the parasite and that this is caused by the shedding of TNF-α receptors. In retinochorditis, one of the most common manifestations of toxoplasmosis, the parasite actually inhibits the production of TGF-β suggesting that the interplay between *T. gondii* and retinal cells may play an important role in this condition (Nagineni et al. 2002). The role of NO in neurodegeneration is also controversial. NO is known to damage neuronal cells but this rarely happens during *T. gondii* infections, possibly because the parasite is able to inhibit the production of NO by microglia through a pathway involving prostaglandin-E and IL-10 (Rozenfeld et al. 2003). Whatever the mechanism, immunity is clearly very important in humans because the majority of the world's population will be infected at some time and that those that are immunoincompetent (e.g. the fetus) or immunosuppressed are at particular risk from a fulminating infection. Toxoplasmosis is now regarded as the most common cause of focal central nervous system infection in AIDS patients (Mariuz et al. 1994).

There is no vaccine against toxoplasmosis in humans. Commercial vaccines based on attenuated strains of *T. gondii* have been developed for use in sheep (Buxton 1993), but such a vaccine would be unacceptable for human use. Our understanding of the cytokine network and the development of DNA vaccines have encouraged the possibility of vaccines that might be acceptable for human use and there have been some successes in mice immunized with a plasmid containing a *T. gondii* surface antigen and IL-2 (Chen et al. 2002). Also being developed are DNA vaccines designed to activate CD8 cells (Scorza et al. 2003) and DNA vaccines designed to

stimulate Th1-type responses and the production of IFN-γ (Fachado et al. 2003). However, a vaccine suitable for use in humans is a long way away.

Immunity to blood-inhabiting protozoa

INTRODUCTION

Four important groups of protozoan parasites inhabit the human bloodstream:

1. the African trypanosomes *Trypanosoma brucei gambiense* and *T. b. rhodesiense*
2. the American trypanosome *Trypanosoma cruzi* (but only transiently, it is best regarded as a tissue parasite)
3. the malaria parasites *Plasmodium falciparum*, *P. malariae*, *P. ovale*, and *P. vivax*
4. in rare and accidental infections, *Babesia* spp.

The bloodstream is a dangerous place for a parasite to live as there is continual and intimate contact with the cells and molecules of the immune system, particularly IgM and IgG antibodies and phagocytic cells. The ability to survive in what should be a very hostile environment has attracted the attention of numerous scientists. African trypanosomes have been particularly intensively studied in laboratory animals and this activity has generated a vast literature much of it, unfortunately, largely irrelevant to the human disease. In this section, only those aspects of the immune response directly concerned with human infections are discussed.

AFRICAN TRYPANOSOMES

The African trypanosomes that infect humans are *Trypanosoma brucei gambiense* and *T. b. rhodesiense*, both related to *T. b. brucei*, a trypanosome of wildlife and domesticated animals that does not infect humans (see African trypanosomiasis). Little is known about the acquisition of immunity to trypanosomes in humans, but there is epidemiological evidence that immunity to *T. b. gambiense* does develop, albeit slowly, in human populations (Khonde et al. 1995). *T. b. brucei* has been widely used as a model for both the human and animal disease, largely because it is the only subspecies that is easy to maintain in laboratory mice and because of its similarities to the human forms. Infections with all three subspecies are similar; the parasites live and multiply in the blood and infections are characterized by successive waves of parasitemia representing different antigenic variants. Each trypanosome is covered with a thick glycoprotein coat, the variant surface glycoprotein (VSG). There is an almost limitless repertoire of VSGs, each known as a variable antigen type (VAT), that arise in 1 in 10^6 cells in laboratory syringe-passaged populations and 1 in 100 cells in field isolates. The normal pattern of events is that the parasites multiply in the blood, are destroyed by an antibody-mediated immune response specific to the major VAT, and are replaced by another population of parasites carrying a new VAT (Barry 1997). Each wave of parasitemia is accompanied by an increase in antibody specific to the VAT that preceded it and is responsible for the removal of most of the trypanosome population leaving a minor population that gives rise to the next wave of parasitemia; subsequent waves appear every 5–10 days. The antibody class involved in the destruction of the trypanosomes is IgM, which facilitates agglutination, complement-mediated lysis, and phagocytosis by macrophages and neutrophils. Later in the infection, VSG-specific IgG antibodies are involved in clearing trypanosomes from the tissues (see Sternberg 1998). The destruction of the trypanosomes, however, results in the release of a number of toxic molecules and internal and external antigens that adhere to or accumulate in various host tissues resulting in complex-mediated damage and resultant immunopathological changes which have been well documented in animal studies but have been little investigated in humans.

There is no evidence of protective cell-mediated immunity in African trypanosomiasis but there is some limited evidence that NO, which has an alternative role (see below), can kill trypanosomes possibly only in combination with TNF-α (Mansfield et al. 2001).

Trypanosomes are also enmeshed in the cytokine network and molecules involved in the immune response such as (TGF-β) and IFN-γ can act directly or indirectly on parasites; IFN-γ acts as a growth factor for *Trypanosoma brucei* (see Mansfield et al. 2001). Trypanosomes can also secrete or excrete products that affect cells of the immune system, for example trypanosome-derived lymphocyte triggering factor (TLTF) and trypanosomal macrophage activating factor (TMAF). TLTF induces lymphocytes to produce IFN-γ, which activates macrophages and promotes trypanosome growth, TMAF also stimulates macrophage activity (see Sternberg 1998; Hamadien et al. 2000). The production of TLTF has been demonstrated in the human trypanosomes *T. b. gambiense*, *T. b. rhodesiense* (Bakhiet et al. 1996). All the African trypanosomes are, therefore, potentially caught up in a series of interactions in which trypanosome-derived factors activate both T lymphocytes and macrophages. The net effect is that lymphocyte produced IFN-γ enhances trypanosome growth while other trypanosome-derived molecules induce macrophages to produce molecules that inhibit lymphocyte activation (Figure 3).

Trypanosome infections are accompanied by severe immunodepression to superimposed antigens and concurrent infections even though their hosts are capable of mounting effective specific immune response against trypanosome antigens. Although this phenomenon has been most extensively studied in animals, there is evidence that it also occurs in patients with trypanosomiasis (Greenwood et al. 1973). The underlying basis of

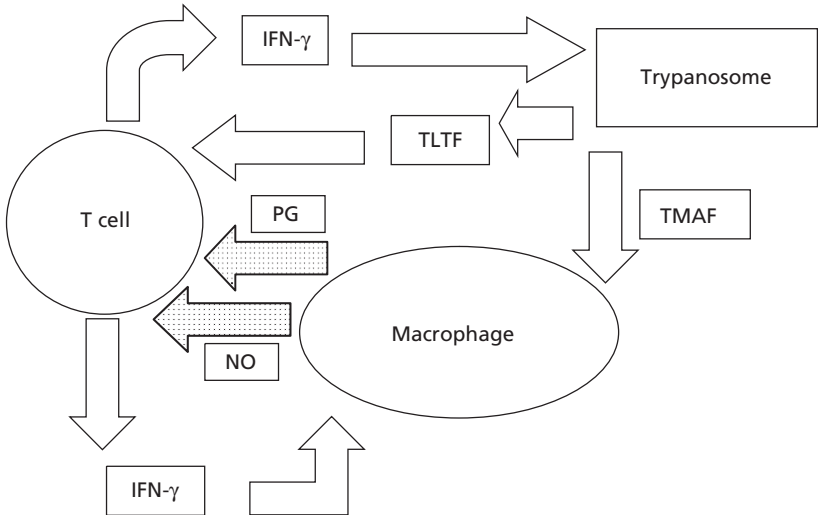

Figure 3 *Diagrammatic representation showing some of the interactions that exist between African trypanosomes and the cytokine network. Trypanosomes produce a number of factors including TMAF and TLTF that stimulate macrophages and lymphocytes respectively. IFN-γ, a product of stimulated lymphocytes, can act as a trypanosome growth factor but prostaglandins (PG) and NO produced by macrophages inhibit lymphocyte activity and hence the production of IFN-γ. Trypanosomes are therefore enmeshed in a network of cytokines and effector molecules that both stimulate and inhibit their growth and development. Positive signals are here indicated by open arrows and inhibitory ones by stippled arrows. (From Cox (2001) with permission from Cambridge University Press)*

this immunodepression is not at all clear but it is thought that impaired B-cell responses may result from overactivation and clonal depletion of B cells from lymph nodes during the course of infection. T-cell activity is also suppressed and this is thought to result from the development of immunosuppressive macrophages and the production of NO and prostaglandins.

The whole field of the immunology of trypanosome infections is a very controversial one and the traditional view that anti-VSG antibody is entirely responsible for the remission of the infection, albeit temporarily, has been challenged by several workers including Mansfield (1994), Mansfield et al. (2001), and de Baetselier (1996) based on in vitro observations and studies in mice. Mansfield suggests that macrophage-derived NO affects the survival of the trypanosomes and also inhibits T-cell function, leading to immunodepression. de Baetselier maintains that the trypanosomes induce CD8 T lymphocytes to produce IFN-γ and macrophages to produce TNF-α and that these synergize to produce toxic molecules that both adversely affect the trypanosomes and cause immunodepression. It is now clear that the traditional picture of antibody-mediated immune responses eliminating variant specific antigens and clearing successive parasitemias is not the whole picture (Mansfield et al. 2001). It is also not at all clear what the situation is in humans, whether or not there is any immunodepression and, if so, if it has any affect with respect to intercurrent infections such as HIV.

MALARIA PARASITES

Malaria is generally recognized as the most important parasitic disease, both in terms of mortality and morbidity (see Malaria). Humans harbor four species of malaria parasite, *Plasmodium falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*, in order of clinical importance. *P. falciparum* is the most intensively studied parasite and, unless otherwise specified, is the only one considered here. The control of malaria has largely depended on the combined use of insecticides and drugs but resistance has made these ineffective and attention has turned to the possibility of developing a vaccine. An important spin-off of this work has been the realization that much of the pathology of malaria is closely associated with immunity, in particular the involvement of cytokines. Research into immunity and immunopathology has resulted in a massive literature reaching tens of thousands of papers, mostly based on rodent models and in vitro systems, much of it, particularly many of the extrapolations made, irrelevant or peripheral to the human situation (Cox 1988). Until recently, our understanding of the ways in which humans react to infection with human malaria parasite has remained a mystery, but success in cloning the *Plasmodium* genome and the application of molecular techniques directly to the human malaria parasites is beginning to pay dividends. However, there are a number of things that we do not understand and our ignorance of these areas hinders our ability to develop vaccines or ways of ameliorating the pathology associated with the disease.

The starting point in our understanding of immunity to malaria is that from epidemiological studies it is known that:

- malaria infections are long-lived, 1–2 years in the case *P. falciparum* and 3–50 years for *P. malariae*

- individuals can be reinfected after natural recovery or cure
- there is a gradual build up of immunity over a period of many years
- any immunity fades quickly
- immunity is largely strain-specific
- children born to immune mothers are themselves resistant to that particular strain of malaria.

In summary, immunity to malaria can be considered to be the rule, although it is often incomplete and may take many years and numerous exposures to the bite of infected mosquitoes to develop. Thus, there is evidence of some immunity and the real challenge is to try to understand the mechanisms involved in order to develop effective vaccines.

In order to understand the immunology of malaria, it is necessary to describe the life cycle (see Malaria for further details). The life cycle of *P. falciparum* begins when the infective stages, sporozoites, are injected by a mosquito directly into a capillary in the skin. The sporozoites circulate in the blood for 30–45 min before they enter liver cells where they undergo a phase of pre-erythrocytic schizogony involving repeated nuclear divisions resulting in the production of about 30 000 uninucleate merozoites after 6–7 days. The merozoites flood into the blood and actively attach to and invade red blood cells within about 20–30 seconds and initiate the erythrocytic stage of the life cycle (see Bannister and Mitchell 2003). Inside the circulating red blood cell, the merozoite feeds on hemoglobin and transforms into a uninucleate feeding stage called a trophozoite; the nucleus then begins to divide and, in *P. falciparum* infections but not in other species, the infected cells disappear from the circulation and adhere to endothelial cells of various internal organs. This process is known as sequestration and is very important in the pathology of the disease. Nuclear division occurs until a schizont containing about 16 merozoites is formed; the merozoites break out of the cell and invade new cells, a process that is repeated almost indefinitely. The liberation of parasites from the red cell is accompanied by the release of a number of toxic molecules, some of host origin and some of parasite origin, that are responsible for some of the pathology associated with malaria. Some young merozoites do not develop into schizonts but into male and female gametocytes that circulate in the peripheral blood until they are taken up by a mosquito when it feeds. Within the mosquito, the gametocytes mature into male and female gametes, fertilization occurs and a zygote called an ookinete is formed. Finally, there is another phase of multiplication resulting in the formation of sporozoites that migrate to the salivary glands and are injected when the mosquito feeds on a new host. The life cycles of the other malaria parasites of humans differ in the length of the pre-erythrocytic and erythrocytic phases, the numbers of merozoites produced and the absence of sequestration. Some strains of *P. vivax* have a persistent dormant pre-erythrocytic phase.

Each stage in this complex life cycle is antigenically distinct and a potential target for immune attack. The malaria parasite is most susceptible when the sporozoite is circulating in the blood, when merozoites are liberated from the liver into the bloodstream before they invade the red blood cells, and when merozoites have been released from red blood cells. The sporozoite is the obvious first target for immune attack. It is the first stage in the infection and the parasites are free in the blood for up to 30–45 min. The sporozoite possesses an immunodominant 40–60 kDa protein surface coat, the circumsporozoite protein (CSP), characterized by a repeat region consisting of four amino acids repeated 37 times, and three or four copies of a smaller repeat dispersed throughout the molecule. In *P. falciparum*, the amino acids of the dominant repeat are asparagine–alanine–asparagine–proline (NANP), and the minor repeat is asparagine–valine–aspartate–proline (NVDP). Other malaria parasites have similar repeat regions but with different amino acid sequences. The CSP is very antigenic and elicits a strong antibody response and has, therefore, been a favorite for vaccination studies. When exposed to antibody, however, the surface molecules are cross-linked and the sporozoite sheds the coat and escapes; thus, it is now thought that the repeat sequence may be a mechanism whereby the parasite evades the immune response by putting up a powerful 'smoke screen' that deflects the response away from more important targets. The repeat region of the CSP is not the only possible target; there are a number of other sporozoite antigens from nonrepeat regions and also those involved in the penetration of the hepatocytes. One of the most important is the thrombospondin related adhesion protein (TRAP) that is involved in sporozoite motility (Sultan et al. 1997).

It was previously thought that, once in the liver, the parasite was safe from immune attack but, in murine malaria models, there is now evidence that there is a Tc cell response to the early stages in hepatocytes and that what is recognized are parasite antigens in the presence of a hepatocyte MHC class I molecule (Tsuji and Zavala 2003). Although we do not know what happens in humans, there is evidence that in West Africa the outcome of infection is controlled by the MHC class I molecules, thus there has been increased interest in antigens associated with the liver stages. The best studied pre-erythrocytic-stage antigens are the liver-stage antigens (LS-A), LS-A1, and LS-A3 but at least 15 more have been identified some of which have some homologies with antigens of other stages in the life cycle (Grüner et al. 2003).

The erythrocytic stages, particularly the merozoites, have received the most attention. They are the easiest to study, they are responsible for much of the disease and

they are obvious targets for attack. A vast amount of information about these stages has been accumulated and many of the antigens involved have been characterized and cloned. The best studied antigen is the merozoite surface protein (MSP)-1, found in all the malaria parasites studied to date; it is a glycoprotein with a molecular weight of c. 190–195 kDa. Experimentally, antibodies against MSP-1 block red blood cell invasion, thus this could be a major target for immune attack and for exploitation as a vaccine. Unfortunately, there is considerable diversity in MSP-1 between isolates, and immunity to one isolate does not confer immunity to another. Other *P. falciparum* antigens of importance are apical membrane antigen (AMA)-1, erythrocyte binding antigen (EBA)-175, serine rich antigen (SERA), and ring-infected erythrocyte surface antigen (RESA), all of which are involved in binding to or invading red blood cells. The erythrocyte membrane protein (EMP), PfEMP-1, found on the surface of late-infected red cells is involved in sequestration and undergoes antigenic variation and is, therefore, thought to be in part responsible for the recrudescences that occur in falciparum malaria (Gatton et al. 2003). The actual role of PfEMP-1 is unclear but it is thought that sequestration prevents infected erythrocytes from circulating through the spleen thus protecting them from the killing mechanisms that appear to operate there. Antibodies against PfEMP-1 prevent sequestration and facilitate parasite destruction in the spleen.

The antigens associated with the sexual stages would seem to be unlikely targets for immune attack but, in fact, they are very important. There are a number of antigens associated with the gametocytes, the male and female gametes and the zygote and, unlike most of the other antigens of malaria parasites, they are very susceptible to antibody attack. This only happens when the gametocytes are taken up by a mosquito together with antibodies in the serum. When the gametocytes escape from the infected red cell they are recognized by the antibodies and are either killed or inactivated. In either case, the infection in the mosquito cannot continue. The antigens of most interest are: a 250 kDa antigen on the gametocytes, gametes and zygote; a 25 kDa antigen on the gametes and zygote; and a 48 kDa antigen on the zygote and oocyst.

The targets for immune attack are, therefore, numerous and complex and the immune responses involved must also be correspondingly numerous and complex. Virtually all Th1 and Th2 components of the immune system are involved at some stage during an infection. Although many details are missing, we now have a very good idea of the overall immune response during the blood stages of a malaria infection. The first time an individual becomes infected with malaria, parasite antigens stimulate NK and T cells to produce low levels of IFN-γ that activate macrophages to produce TNF-α, ROI, and NO. All three molecules have been implicated in the killing of intra-erythrocytic parasites but the strongest evidence supports the role of NO as the key molecule in this process (see Clark and Cowden 2003). Whatever the actual mechanism, these non-antibody molecules, possibly in combination, bring the infection under control with few clinical symptoms. Where the destruction of parasites occurs is not known but it does not seem to be in the circulating blood: the most likely site is the spleen and evidence for this comes the observation that individuals who have had their spleens removed often have difficulty in controlling the parasitemia. It is possible that the flow of blood is slowed down in the spleen and the infected erythrocytes come into close contact with macrophages lining the blood vessels thus causing the release of pro-inflammatory cytokines and NO that damage the intra-erythrocytic parasites while infected cells and free merozoites are phagocytosed.

On exposure to a subsequent infection, the primed T cells produce larger amounts of IFN-γ that induces macrophages to produce excessive amounts of the pro-inflammatory cytokines, IL-12, IL-18, and TNF-α, leading to the symptoms associated with severe malaria. In individuals who recover, the immune system switches to the production of antibodies, mainly IgG2 and IgG3, which impede red blood cell invasion, inhibit parasite multiplication, enhance phagocytosis of merozoites and infected cells, and neutralize toxins (Garraud and Perraut 2003). At the same time, Tr cells produce anti-inflammatory cytokines, IL-10 and TGF-β, which down-regulate the production of TNF-α by macrophages and bring about amelioration of the symptoms of severe malaria. It is important to note that the different roles of Th1 and Th2 cytokines do overlap, for example IL-4, IFN-γ, and TGF-β are involved in the production of IgG1, IgG2a, and IgGb respectively (Stavnezer 1996).

The erythrocytic stages are not the only targets for immune attack; the early stages in the liver are other possible targets. The completion of the *Plasmodium* genome project has resulted in the description of a plethora of liver-stage antigens (see Grüner et al. 2003; Taylor-Robinson 2003). Immunity to liver stages is very difficult to investigate in humans but the only antigen expressed specifically by infected hepatocytes is LSA-1, thought to be the target for Tc cells or NK cells (Schmieg et al. 2003). Interest in the sporozoite antigens has also not waned, although attention has shifted towards the possibility of incorporating such antigens into multicomponent vaccines. Similarly, antigens from the sexual stages are now being considered as possible components of multistage vaccines (see below).

The complexity of the immune response means that inevitably some of the reactions will be adverse ones and the main manifestations of severe malaria, metabolic acidosis, cerebral malaria and anemia correlate with circulating levels of the pro-inflammatory mediator TNF-α. There is now incontrovertible evidence that

severe malaria is caused, in part at least, by NO elicited during the protective immune response (Clark and Rockett 1996). The arguments that have gradually led to this conclusion are complex; further information is to be found in the comprehensive review by Clark and Cowden (2003). It is now also clear that in cases of severe malaria, NO as evidenced by the presence of iNOS, is present in many tissues of the body suggesting that the disease is a multi-organ one (Clark et al. 2003). The realization that protective immune responses may have deleterious side-effects has serious implications for the development of a vaccine against malaria.

The development of a vaccine must take into consideration what stage of the parasite life cycle to attack and what kind of antigens to use. The life cycle of the malaria parasite is very complex and includes a number of stages that are biochemically and immunologically distinct. Immune responses against all these stages have been detected but immunity against one does not protect against the next. In effect, malaria infections consist of a sequence of different infections, not just one.

The antigens are complex: each stage possesses a large number of different antigens some of which are protective and some of which are not. In addition, malaria parasites have evolved a number of ways to evade the immune response so some of the antigens identified could be counter-protective. Research on malaria vaccines has paralleled or, in some cases, led research on viral and bacterial vaccines and the emphasis has changed with our increasing understanding of the immune response as a whole. The traditional approaches have been to identify and characterize potentially protective surface antigens and to use these as:

- subunit antigens on their own
- as a basis for synthetic vaccines
- as recombinant molecules expressed in a suitable vector.

All three methods have been tried with varying success over the past two decades and this subject has been extensively reviewed (Hoffman 1996; Facer and Tanner 1997; Good et al. 1998; Miller and Hoffman 1998; Ballou et al. 1999; Anders and Saul 2000; Plebanski and Hill 2000). More recently, there has been a switch to the possibility of DNA vaccines and prime-boost methods of immunization whereby the host is first immunized with a DNA vaccine expressing the requisite antigens and subsequently with a recombinant vector expressing the same antigens.

Sporozoites are obvious targets, being the first stages to enter the body and circulating in the blood for a short time before entering the liver; a vaccine against the sporozoite should prevent infection. The first vaccines against malaria consisted of irradiated sporozoites (Clyde et al. 1973) and it soon became clear that the immune response was directed against the NANP repeat region of the major surface protein of the sporozoite, CSP. The NANP repeat was then used as a basis for recombinant vaccines expressed in *E. coli* (Ballou et al. 1987) and for synthetic vaccines (Herrington et al. 1987) in a number of trials with potentially promising results – about 20–30 percent of volunteers were protected. However, these trials also revealed that there was little correlation between antibody levels and protection. It is now widely accepted that the sporozoite repeat antigen is not a good vaccine candidate because if even one sporozoite escaped into the liver an infection would be initiated. In addition, the epidemiological evidence does not support the concept that a sporozoite vaccine would be effective. Returning to vaccines based on irradiated sporozoites, it was found that high levels of irradiation prevented sporozoites from invading liver cells and that exposure to such sporozoites was not protective, so attention moved on to sporozoite antigens involved in hepatocyte invasion. A promising recombinant vaccine called RTS,S and consisting of part of the CSP fused to the hepatitis B surface antigen was developed in the Gambia with excellent results (over 70 percent efficacy); unfortunately, this protection faded after about 15 weeks (Bojang et al. 2001). Modifications of this vaccine are now being developed for possible clinical trials. All these vaccine trials were based on eliciting antibody responses but attention has now turned towards T-cell responses (Taylor-Robinson 2003). It was once thought that there was no immune response against the liver stages but it is now apparent that there are immune responses in the liver that block the invasion of the hepatocytes and probably kill the early stages of the parasite within the hepatocytes (Aidoo and Udhayakumar 2000). Several liver-stage antigens are now recognized, particularly LSA-1 and LSA-3, as possible targets for immune attack and there have been several attempts to incorporate them into multicomponent vaccines. The most promising developments are concerned with DNA vaccines and the current front runner is a vaccine based on a string of 20 T- and B-cell epitopes derived from *P. falciparum* pre-erythrocytic-stage antigens fused with the TRAP molecule plus the modified vaccinia virus Ankara (MVA) (Moorthy and Hill 2002). This DNA ME-TRAP vaccine is now undergoing clinical trials with different prime-boost regimens (McConkey et al. 2003). Similar vaccines with the fowlpox virus FP9 substituted for MVA and the possibility of boosting the response to RTS,S are also at various phases of development and clinical trial (Moorthy and Hill 2002).

Blood stages are obvious vaccine targets because there are so many of them and because they cause the disease. A number of potential antigens have been recognized, either associated with the infected red cell, intra-erythrocytic parasites, merozoites or secreted soluble antigens. The prime targets are the antigens involved in adhesion and red blood cell invasion. A vaccine against the adhesion molecule, PfEMP-1, would

prevent or decrease the pathology associated with sequestration but, because of the ability of PfEMP-1 to undergo antigenic variation, it is not a suitable vaccine candidate. Attention has, therefore, focused on antigens involved in red cell invasion. A recombinant form of MSP-1 has been assessed in Phase I and Phase II (safety and efficacy) trials but was found to produce adverse hypersensitivity effects (Keitel et al. 1999). However, MSP-1 together with other antigens, is being considered as a component of multicomponent vaccines incorporating the genes for antigens from various stages of the life cycle, including the sporozoite, liver, erythrocytic and sexual stages (Holder 1999; Shi et al. 1999). A number of multicomponent vaccines have been developed of which the most extensively studied is one based on three blood-stage antigens (MSP-1, MSP-2, and RESA), which has produced some encouraging results in field trials in Papua New Guinea (Genton et al. 2003).

Currently, the only vaccine that has been subject to extensive field trials is SPf66, a synthetic vaccine consisting of a polymer of three merozoite antigens: Pf83 (an 83 kDa peptide representing part of MSP-1), Pf55, and Pf35. These antigens, none of which has been identified with any of the known major malaria antigens, are linked together by the sporozoite antigen NANP (Valero et al. 1993). In a number of extensive trials in Colombia, Ecuador, and Venezuela, the results obtained indicated that the vaccine was safe and immunogenic and, although it did not prevent malaria, it reduced the number of malaria episodes. It has also undergone extensive trials in natural populations of children in Africa and adults in Thailand but, unfortunately, it did not prevent malaria in children in trials in Tanzania (Beck et al. 1997) or The Gambia (Bojang et al. 1998). SPf66 is the only malaria vaccine that has so far been approved by the WHO but has now been discontinued in its original form.

One of the possible vaccine components is the sexual stage in the mosquito (Targett 1995). At first, this might seem to be a very strange target for attack but it is both logical and feasible. The principle is to immunize individuals with sexual-stage antigens to raise antibodies that inactivate the sexual stages when taken up in the serum by a mosquito. This has been called the transmission blocking or 'altruistic' vaccine because it does not protect the person immunized although it does prevent transmission. Pfs25 and Pfs28, antigens on the surface of the malaria zygote, are the most favored candidates for such a vaccine and a recombinant fusion protein, TBV25-28, containing these two antigens has been developed and considered for clinical trials (Gozar et al. 2001). Up to now, the idea of such a vaccine would have been unthinkable but there is no reason why such a transmission blocking antigen should not be added to another vaccine such as SPf66.

Numerous other possibilities are currently being pursued and it will probably be necessary to have a multipronged approach to the development of a malaria vaccine. It may not be necessary to produce sterile immunity but it might be possible to reduce the severity of the infection. It may, therefore, be possible to consider novel approaches such as vaccinating against the disease rather than the infection and there is some evidence that it is possible to immunize laboratory animals against the toxins produced by malaria parasites (Schofield et al. 2002).

The development of a malaria vaccine has been a long and frustrating search with many false starts and unachievable promises. The future, however, is brighter and depends on scientific co-operation rather than competition which is now forthcoming (Medaglini and Hoeveler 2003; www.niaid.nih.gov/dmid/malaria/malariavac.htm).

BABESIAL INFECTIONS

Babesiosis, although common in wild and domesticated animals, is a rare accidental infection in humans (see Babesiosis of humans). Little is known about immune responses in humans except that immunologically intact individuals are susceptible to infection with the rodent babesia *Babesia microti*. Immunity seems to be similar to that seen in malaria in that it involves the activation of macrophages and NK cells and the production of NO (Aguilar-Deflin et al. 2003). Such infections are accompanied by raised specific antibody levels, even in the presence of persisting parasitemias, a phenomenon common in many protozoal infections. Babesiosis caused by *B. microti* is more serious in immunologically compromised patients and the European form, caused by *B. divergens*, has been reported only from splenectomized individuals, suggesting that an intact immune system is required to keep this infection under control (see Telford et al. 1993). Although nothing is known about the ways in which *Babesia* spp. survive in humans, it is known that there are a number of ways in which these parasites survive in other hosts; these include antigenic variation, cytoadhesion to avoid immune attack (as in malaria infections), binding of host proteins to infected red blood cells and immunodepression (Allred 2003). The persistence of babesial infections and the ability to sequester suggest that the pathology of babesiosis might resemble that seen in malarial infections (see Clark and Cowden 2003).

Immunity to tissue-inhabiting protozoa

Several parasitic protozoa occur in human tissues, including the following:

- the ubiquitous coccidian *Toxoplasma gondii*, in a variety of nucleated cells, including macrophages, and the brain
- *Trypanosoma cruzi* in muscle and nerve cells
- *Sarcocystis* spp. in muscle
- microsporidians in various tissues including the brain

- opportunistic amebae in the brain.

Of these, *T. gondii*, already discussed, and *T. cruzi* are the most important and, partly because of the ease with which they can be maintained in laboratory animals, have been the most intensively studied. The remaining tissue-inhabiting protozoa cause long, chronic and usually harmless infections but these may become fulminating in immunologically compromised individuals such as those co-infected with HIV.

CHAGAS DISEASE (NEW WORLD TRYPANOSOMIASIS)

Chagas disease, caused by the trypanosome *Trypanosoma cruzi*, is confined to South and Central America (see WHO 2002; New World trypanosomiasis). *T. cruzi* infects more than 150 species of mammals and most of the research done with this parasite has been carried out in rodents, particularly mice, in which the pattern of immunity that emerges is complex and is influenced by the genetic make-up of both the parasite and host. Chagas disease is one of the most insidious of all parasitic diseases. The infection is transmitted by blood-sucking bugs and is typically acquired in childhood; the victim may experience little more than a localized swelling and a transient fever but, in some individuals, possibly as many as 20–40 percent, the infection may be acute and life threatening. Adults who become infected tend to develop a life-long chronic infection which can result in death many years later. The trypanosomes divide at the site of the bite and circulate briefly in the blood before entering macrophages, in which they develop into nonflagellated amastigotes and survive by escaping from the phagolysosome and multiplying in the cytoplasm of the cell. From there, they escape and invade other macrophages or a variety of other nucleated cell types, including muscle cells (particularly cardiac muscle) and nerve cells. There is a strong immune response in individuals who survive an acute infection but this is only partially effective and does not eradicate all the parasites; the infection, therefore, persists throughout the life of the host. During the course of the infection, the host mounts specific antibody responses involving all subclasses of immunoglobulins. As in most other infections, there is an early rise in IgM followed by increasing levels of IgG, which persist throughout the infection and are, therefore, useful for diagnosis.

The use of genetically modified mice has made it possible to examine the immune response to *T. cruzi* in some detail (Tarleton et al. 2000). In mice, high levels of IgG2a, IgM, and IgE persist for about 13 weeks after which IgG2a and IgM levels begin to decline but, together with IgG1 and IgG2b, remain elevated throughout infection (Rowland et al. 1992). Studies in mice have also provided clues about cell-mediated immune responses to *T. cruzi* (reviewed by Takle and Snary 1993; Kierszenbaum and Sztein 1994; Kirchoff 1994). Protective immunity to *T. cruzi* is T-cell dependent and cell-mediated (Wrightsman et al. 2002). The main defense mechanism is provided by macrophages activated by TNF-α, IFN-γ, and IL-12 resulting in the production of NO, which is responsible for the killing of intracellular parasites (see Machado et al. 2000; Talvani et al. 2003). However, this activity can be inhibited by IL-4, IL-10, and TGF-β (Munoz-Fernandez et al. 1992; Gazzinelli et al. 1992; DosReis 1997; Reed 1998). There is no clear-cut Th1 and Th2 polarity in *T. cruzi* infections and it appears that Th1 cells are required for the control of infection and that Th2 cells may be involved in the persistent parasitemia and severity of disease (Kumar and Tarleton 2001).

The long-term persistence of parasitemia is a characteristic feature of Chagas disease and it is clear that *T. cruzi* survives for the whole lifetime of patients with chronic Chagas disease as evidenced by the fact that, at autopsy, parasites have been detected in heart muscle (Brener 1994), smooth muscle and adrenal glands (Teixeira et al. 1997). The parasite can only survive by evading the immune response and this is partially achieved inactively by forsaking macrophages and invading nonphagocytic cells. *T. cruzi* also evades the immune response actively in a number of ways. Antibody attack is prevented in two ways: the inhibition of antibody binding, and the inhibition of complement activation. Antibody binding is inhibited by the overproduction of nonprotective IgM that interferes with the binding of potentially protective IgG; complement activation is inhibited by means of a surface glycoprotein that binds C3 (the third component of complement) and thus inhibits both the classical and alternative complement pathways (Beucher et al. 2003). *T. cruzi* also employs a variety of immune evasion mechanisms to enable it to avoid cell-mediated immune responses (Zambrano-Villa et al. 2002). The production of IL-12 and TNF-α (essential for parasite killing) is inhibited by a parasite surface antigen, AgC10, that binds to the surfaces of macrophages (de Diago et al., 1997); another parasite molecule promotes the production of IL-10 and TGF-β (Sztein et al. 1990) while also inhibiting the production of IL-12 (Silva et al. 1998). Immunosuppression is also characteristic of *T. cruzi* infections and this is brought about, in part, by the induction of a population of suppressor cells (Tarleton 1998). In the context of immune evasion, it might be to the advantage of the parasite to mimic host antigens but one possible outcome of the possession of shared antigens is autoimmunity, which some authorities consider to be characteristic of this infection.

Chagas disease is life-long and usually chronic and is accompanied by the gradual destruction of the infected cells, giving rise to cardiac failure and loss of control of the digestive system later in life, possibly 20–30 years later (Tarleton 2001). Whether or not Chagas disease is

an autoimmune disease is a matter of controversy (Leon and Engman 2001), but the histopathological picture does suggest an autoimmune phenomenon. Sequestered antigens released when infected cells are destroyed and uninfected cells onto which *T. cruzi* antigens have been adsorbed are potential causes of autoimmunity. In experimental animals, autoantibodies appear after nerve cells have been destroyed, antibodies to rat ganglia cross-react with *T. cruzi* and anti-*T. cruzi* antibodies cross-react with mammalian tissues. Comparable observations have been made in patients with Chagas disease, for example the C-terminus of the *T. cruzi* ribosomal P protein shares epitopes with host cells (Mahler et al. 2001) and myosin shares epitopes with the *T. cruzi* B-13 antigen with evidence of some association with chronic chagasic cardiopathy (Cunha-Neto and Kalil 2001). There is further information on the pathology of Chagas disease in New World trypanosomiasis.

In summary, immunity to *T. cruzi* involves some of the most complex immunological responses encountered in any infection involving antigens, host cells, chemokines and cytokines (see Teixeira et al. 2002); the interplay between immunity, immune evasion, and autoimmunity is likely to take many years to elucidate. In the meantime, although some experimental vaccines have been developed, the possibility of a protective vaccine that does not cause any autoimmunity against this important human pathogen seems remote.

MICROSPORIDIANS

Microsporidiosis, caused by at least eight species belonging to five genera (see Microsporidiosis) is a rare but increasingly recognized condition in immunologically compromised patients, particularly those suffering from AIDS (Bryan 1995; Deraedt and Molina 1995). As the condition is virtually unknown in immunologically competent individuals, there must be some immune response that keeps these infections under control, but definite evidence for this, and its mechanisms, is lacking. Apart from the epidemiological evidence, most of our knowledge comes from animal and in vitro studies, which might not be relevant to what happens in humans. It is clear that perturbation of T-cell function is a major cause of immunological failure leading to microsporidiosis, but as T cells are central to so many immunological responses, it is difficult to draw firm conclusions about the nature of natural or acquired immunity to microsporidiosis in humans.

SARCOCYSTIS AND RELATED ORGANISMS

Little is known of these rare infections in humans (described in *Sarcocystis*) in terms of the immune responses that they evoke in their natural hosts, laboratory animals or humans. All form thick-walled cysts with few signs of any immunological reaction or immunopathology.

OPPORTUNISTIC AMEBAE

Although these free-living amebae (belonging to the genera *Acanthamoeba*, *Balamuthia*, and *Naegleria*) are sometimes grouped with the intestinal amebae, it is convenient to consider them briefly here. As there have been relatively few human infections, there is very little information available and it is not known whether or not individuals mount a protective immune response. If they do, it is not clear whether this protects against subsequent infection (which, in any case, would be very unlikely). Virtually all that is known is that specific antibodies have been detected in the sera of infected individuals (see Opportunistic amebae). Information that has accrued from observations in animal models has been reviewed by John (1993).

IMMUNITY TO HELMINTHS

Characteristics of helminths in relation to the immune response

Helminths (worm parasites) confront the immune system with problems that are quite different from those posed by protozoa. These problems are largely the consequences of greater size and structural complexity, but are compounded by three additional factors:

1. worms have the ability to move actively through the body of the host
2. as part of their life cycles, many undergo sequential developmental changes in the host, during which their structure and antigenic make-up may change dramatically
3. their bodies are covered by layers that are more complex and less vulnerable to immune attack than conventional plasma membranes.

Thus, although helminths occupy many of the sites in the body that are exploited by protozoa (other than the truly intracellular), the immune mechanisms required to destroy them in or remove them from these sites must often be qualitatively different. Unlike protozoa, the majority of helminths do not replicate within the host. In these circumstances, an increase in the worm burden carried (and the associated danger of pathology) occurs only when the host is repeatedly infected. Under conditions of natural infection, immune responses are, therefore, most important in preventing or reducing reinfection. There are, however, some helminths in which the numbers of parasite stages present in the body do increase after infection. These include:

- tapeworms, such as *Taenia solium* and *Echinococcus*, in which an initial infection may produce large numbers of larval stages
- the blood flukes (*Schistosoma*), in which eggs become trapped in tissues

- the nematodes, *Strongyloides* and *Trichinella*, in which larvae accumulate in the body.

In such cases, the development of the immune response can be considered analogous to that which occurs in protozoan infections.

Adult stages of helminths range in length from a few millimeters to several meters. Larval stages may be less than 1 mm in length, but even the smallest larva is too large to be phagocytosed or lysed by a single cell; cytotoxic activity, therefore, requires multiple interactions between the parasite surface and inflammatory cells. Such interactions can be mediated by both complement and antibody, ADCC being a common response to invasion by worms.

In addition to being large, helminths are complex multicellular organisms with well developed organs and tissues. When alive, they present the immune system with a diverse range of antigens, both on their surfaces and in excretory and secretory products. When they die, many more antigens may be released. Although immune responses are made to the majority of these antigens, they may have little or no effect on the parasite for some or all of the following reasons:

- the molecules concerned may not be essential for worm survival
- in the living worm, these molecules may be inaccessible to effector mechanisms
- the response to released antigens may take place at a considerable distance from the parasite
- the parasite may actively move away from the immune response generated at a particular site
- the antigens may elicit inappropriate immune responses
- the parasite may evade, inactivate or down-regulate immune effectors.

In general then, although there are important exceptions involving larval stages, worms are likely to be much less easily controlled by immediate interactions with immune effector mechanisms than are protozoa. Binding of antibodies or surface activation of complement rarely kills worms directly; effective immunity is more often the indirect result of immunologically specific recognition events. Among the more important of these are ADCC, immune-mediated inflammation, and antibody-mediated inhibition of enzyme activity.

The result of ADCC reactions is the adherence of large numbers of cells and the release onto the surface of a variety of enzymes and short-range mediators. These may harm the parasite directly, either by destroying the integrity of the surface layer or by causing damage to deeper tissues. The effectiveness of such attack is influenced by the nature of the surface available. For example, whereas flukes such as schistosomes have relatively delicate cytoplasmic surfaces, nematodes have tougher collagenous cuticles that provide them with considerable protection against external damage. Larval nematodes may be killed by ADCC, but adults are often unaffected. Even the theoretically more vulnerable schistosomes have multiple evasion strategies that result in their surfaces being difficult to damage. In addition, effective ADCC requires not only that cells bind to the target, but also that the cells maintain contact, which is sometimes difficult when the target is an active worm.

With the important exceptions of tapeworms and acanthocephalans, most helminths feed actively and digest their food source enzymatically, either within their own intestines or externally before uptake. The enzymes used in these processes can be important targets for the host immune response, as are those used by worms to penetrate the host and to move through its tissues. The interaction of antibodies with target parasite enzymes can inhibit their activity, which can prevent successful invasion, migration, growth, and development and may result in worm death. Indeed, the complex nutritional, environmental, and behavioral requirements of worms make any host-mediated interference with normal function a potential means of increasing resistance.

By mechanisms that are not fully understood, the range of immune responses elicited by infections with helminths typically show a number of important differences from those generated by protozoan infections. Both in humans (Yazdanbakhsh et al. 2001, 2002) and experimental rodents (Gause et al. 2003), helminth antigens elicit responses that are predominantly mediated through cytokines released from lymphocytes of the Th2 subset. Prominent among these responses are the increased production of reaginic antibody (IgE), mast cells and eosinophils. Immediate hypersensitivity reactions, in which these components are involved, are therefore characteristic accompaniments of worm infections, but rare in protozoa. The inflammatory consequences of such reactions can be very effective forms of host defense and provide substantial resistance to infection. They result in structural, functional, and biochemical changes in the tissues surrounding the worms and lead to the release of powerful biologically active mediators. If antigenic stimulation and inflammation persist, worms may become the focus of cellular accumulations that trap them and that may ultimately kill them. As well as endangering the parasite, such chronic reactions may also cause severe host pathology. In a number of infections (e.g. schistosomes, filarial nematodes, larval cestodes), the parasites release factors that lead to down-regulation of the immune response, IL-10 playing an important modulatory role. In this way, parasites protect themselves from the host response and prolong their survival.

One of the most interesting experimental models of helminth infection is that of the intestinal nematode *Trichuris muris* in mice. As with the protozoan

Leishmania major, there is a reciprocal relationship between the Th subset response and immunity but in the case of *T. muris*, Th2 activity leads to resistance and Th1 to continuing susceptibility – i.e. the opposite of what happens in *L. major* infection. The dependence of the host response to *T. muris* on specific cytokines is elegantly demonstrated by the fact that the phenotypes of genetically susceptible and resistant mice can be reversed by injection of the appropriate cytokines or anticytokine reagents (Else et al. 1994). Although these 'helminth-type' and 'protozoan-type' patterns are clear cut in certain experimental models, in the majority of species of both groups the interrelationship between Th1 and Th2 responses appears to be more complex.

It should, therefore, be clear that although protozoa and helminths are grouped together as 'parasites' and both are powerfully immunogenic to the hosts, if they are to be successfully controlled by immune responses rather different strategies are required and quite distinct mechanisms may be involved.

Immunity to intestinal helminths

The characteristics of the intestine as an environment for parasites have already been described (see Immunity to intestinal protozoa). Despite the many defenses that can act there, the intestine is one of the commonest environments for parasitic worms and it is colonized by representatives of all the major groups: digeneans (flukes), cestodes (tapeworms), and nematodes (roundworms). Relatively little is known of immune responses to intestinal flukes and tapeworms in humans. More is known about nematodes, but most of this information concerns responses that can be measured peripherally, i.e. antibodies, proliferative and cytokine responses of circulating lymphocytes, delayed hypersensitivity and inflammatory responses. For an insight into responses operative at the intestinal level, we are heavily dependent on data obtained from work with experimental models.

INTESTINAL NEMATODES

A very large number of nematode species live in or infect via the intestine. Collectively, they are among the commonest of all parasites, infecting an estimated one-quarter of the world's population (see

Gastrointestinal nematodes – *Ascaris* hookworm, *Trichuris*, and *Enterobius*). The major intestinal nematodes of humans (*Ascaris*, hookworms, *Strongyloides*, and *Trichuris*) all mature in the intestine, but reach that site in a variety of ways. *Trichuris* infections are established by ingestion of eggs and the worms develop directly in the large intestine. *Ascaris* also infects orally, but after hatching, the larval stages penetrate the intestinal mucosa and migrate via the liver and lungs before returning to the small intestine to mature. The larvae of hookworms and *Strongyloides* characteristically infect through the skin and then migrate to the small intestine. In addition to the intestine itself, immunity to worms with migratory stages may, therefore, operate at several sites in the body. The mechanisms likely to be effective are determined by the characteristics of each organ system involved. Immune and inflammatory responses in parenteral sites such as the skin, liver, and lungs share a number of common features. Worms moving through these sites are likely to be in intimate contact with potential effectors, such as antibodies (IgM, IgG), complement, biologically active mediators and cytotoxic cells, and can therefore be damaged directly. In contrast, worms living in the intestine itself may have a quite different relationship with the immune system. Not only does the intestine have distinctive immune mechanisms, but unless worms penetrate into the mucosa they are unlikely to be accessible to some of the effector mechanisms that operate in the tissues. Those effectors that may affect intestinal worms include the antibody isotypes that are secreted into the lumen (IgA and IgM) or leak from the mucosa (IgG), and mediators such as amines, prostaglandins, leukotrienes and reactive oxygen and nitrogen metabolites that are produced by inflammatory cells. Intestinal worms, like all parasites, are wholly dependent on the physical and physicochemical characteristics of their environment, and these conditions may change dramatically when the intestine is inflamed as a result of infection. Such changes can themselves contribute to immunity by making the local habitats of the parasites unsuitable for their continued survival. As already mentioned (see The cytokine network in parasitic infections, and Characteristics of helminths in relation to the immune response), worm infections selectively elicit Th2 subset responses and the cytokines produced by these cells generate powerful responses, components of which (e.g. IgE, mast cells, and eosinophils) are known to be potent mediators of intestinal inflammation.

Experimental systems in laboratory animals show that intestinal worms can be very effectively controlled by host immune responses (Gause et al. 2003). It is much less clear whether or not intestinal worms in humans are similarly controlled. Infections are not only very common, they are often persistent. Individuals may acquire worms early in life, retain worms for long periods, and be easily reinfected. Epidemiological studies indicate that although the prevalence of infections often remains high as people age, the intensity of infection (numbers of worms) can decline significantly (Bundy 1995). This may indicate the operation of protective immune responses, although it is obvious that behavioral changes will also be involved, as transmission of all the major intestinal worms is dependent on some degree of contact with fecal or fecally contaminated material. Cross-sectional analysis of infected populations shows that the parasite burden is aggregated into

relatively few individuals, most having small numbers of worms. Again, this may indicate an effective immunity or may reflect behavioral influences. It is well established that individuals are predisposed to a particular level of infection, i.e. they reacquire worm burdens after chemotherapy that are similar to those existing before treatment. In some, this predisposition results in heavy infections (i.e. the individuals are susceptible); in others, only light infections are acquired (i.e. they appear resistant). Predisposition suggests the operation of genetically determined levels of immunity to infection, and evidence supporting this interpretation is now beginning to appear (Williams-Blangero et al. 2002).

Knowledge of immune responses to intestinal nematodes of humans is much less detailed than that of responses to filarial worms and schistosomes (see Immunity to filarial nematodes, and Schistosomes). In general, correlative immunoepidemiological studies show that serological responses correlate positively with intensity and duration of infection, but certain isotypes appear to be associated with protective immunity. These include IgA responses in *Trichuris* infections (Bundy and Medley 1992) and IgE responses in hookworm (*Necator*) and *Trichuris* infections (Pritchard et al. 1995; Faulkner et al. 2002). The functional roles of antiworm antibodies are uncertain. ADCC responses may be generated against stages migrating through tissues, but the adults in the intestine are large and well protected organisms. Antibodies may interfere with feeding activities, particularly where, as in hookworms and possibly *Trichuris*, these depend on the worm releasing enzymes into the host's tissues. Antibodies may also reduce the effectiveness of worm secretions that interfere with the operation of host defense mechanisms, such as anti-enzymes, antioxidants and immunomodulators (Pritchard 1995). Recent studies have begun to analyze cellular and cytokine responses (Cooper et al. 2000; Geiger et al. 2002; Turner et al. 2002). So far, these have not shown the same clear-cut correlation of protective immunity with T2 cytokines that has emerged from work in animal models (see below). Geiger et al. (2002), for example, found that parasite-free individuals showed higher T1 cytokine production (TNF-α, IL-12, IFN-γ) than infected individuals, whereas T2 cytokines were present equally in parasite-free and infected patients. Both this group and Turner et al. (2002) recorded production of IL-10 in infected individuals, suggesting that chronic infections may be associated with activity of Th3 or Tr cells.

Experimental studies in rodents have given detailed pictures of the nature and operation of immune responses against intestinal nematodes. These may operate during the course of primary infections to expel worms from the intestine. On reinfection, protective responses operate more quickly and may prevent the establishment of infection almost completely. In all cases, immunity is Th cell-dependent, and Th2 cells play the major role, polarization of the response to this subset being critical for protection (Gause et al. 2003). In manipulative experiments, it has been shown that IFN-γ can prevent, and IL-4 together with IL-13 can promote, the normal expression of immunity; IL-10 production is also important to ensure a Th2 bias. The roles of the co-stimulatory and signaling membrane molecules that regulate T-cell activity and define whether host responses are protective or otherwise (e.g. B7.1-B7.2, CD40L, STAT 4/6 and chemokine ligands) have now been fully defined (Gause et al. 2003; deSchoolmeester et al. 2003). Analysis has also extended to the role of intracellular signaling pathways (Artis et al. 2002).

Responses to infection are accompanied by acute inflammatory changes that result in structural and functional modifications of the intestinal mucosa, and in some species (e.g. *Nippostrongylus*, *Strongyloides*, *Trichinella*) these act as important effector mechanisms, (Artis and Grencis 2001). Although IgE antibodies and eosinophilia accompany the intestinal inflammation induced by infection in rodents they do not seem to have a significant role, and deletion of these responses by using antibodies against the relevant cytokines does not affect the expression of immunity. In contrast, mast cells do play an important role against certain species (Helmby and Grencis 2002). In other parasites (e.g. *Trichuris*) antiworm IgA and IgG1 antibodies seem to be important, probably by interfering with important metabolic or behavioral activities. In worms that migrate through the tissues to reach the intestine (*Nippostrongylus*, *Strongyloides*), immunity acts against the intestinal stages during a primary infection, but against tissue stages in subsequent infections, larvae being trapped in inflammatory foci in the lungs or the skin. Similar mechanisms appear to act against migrating larval hookworms in immune mice (Girod et al. 2003).

Experimental models have not only allowed the study of protective responses, they have also shed light on situations in which immunity does not operate or operates at best ineffectively. Some nematodes in mice (like nematodes in humans) establish chronic, long-term infections. With one species (*Heligmosomoides polygyrus*), this is due to immunomodulatory influences exerted by adult worms, which effectively suppress the potentially protective responses elicited by the larval stages. Immunomodulation is associated with the release of particular molecules in the secretions of adult worms. Full expression of this immune suppression is under strong host genetic influences, which determine the speed and nature of antiparasite responses. *Trichuris muris* can also establish chronic infections in certain strains of inbred mice. In most strains, infection elicits Th2 responses that result in effective immunity and worms are lost before they can become mature. In certain strains, the initial Th2 response is switched to a Th1 response and the host is then not only unable to eliminate the existing infection but remains susceptible

to subsequent infections as well, a situation that has many parallels with human *Trichuris* infections (Artis and Grencis 2001). Chronic worm infections are often associated with immunopathological changes to the intestine, which almost certainly reflect the effects of persisting, inappropriate immune responses.

Immunity to filarial nematodes

Filarial nematodes (members of the Filarioidea) are important human parasites in many subtropical and tropical countries (see Lymphatic filariasis, and Onchocerciasis). All are transmitted by insect vectors, which act as intermediate hosts allowing development of larvae to the infective stage. These larvae are transmitted when the insect bites, the initial stages of infection, therefore, involve the skin and dermal tissues. In some species, the adults remain in the superficial layers of the body but in others, the adult worms live within much deeper tissues; both are, therefore, theoretically susceptible to direct interaction with immune effectors such as antibody, complement and cytotoxic cells. There are several species of filariae that infect humans, many of which are of low pathogenicity or of only local significance. The most important species are those in which the adult worm lives in the lymphatic tissues (the genera *Wuchereria* and *Brugia*) and those in which the adults live in the skin (*Onchocerca*). In the former, adult females liberate embryos (microfilaria larvae) that circulate in the blood; female *Onchocerca* release microfilaria into the skin. Biting insects pick up these larvae while feeding, the larvae undergo molts to reach the infective third stage, and these then re-enter the human at the next blood meal. In the lymphatic species, pathology is caused by the adult stages, whereas in *Onchocerca* microfilaria are the primary cause of pathology.

It is characteristic of all filarial infections that they are long-lived; worms survive for many years and release millions of microfilaria. Many individuals in areas where these infections are endemic continue to accumulate worms over long periods. These two features suggest that there is little or no immunity, but more detailed epidemiological studies suggest otherwise. Even in areas where the overall prevalence is high, some individuals are parasitologically negative, show no pathology but do have antiparasite immune responses, indicating exposure to infection. The majority show signs of infection, of pathology, or both. Some are heavily infected, with many circulating microfilaria, but may have relatively little overt pathology; some have severe pathology but may have few or no microfilaria in the blood; others may have low microfilaremia but show abnormal pathology indicative of hypersensitivity reactions. Collectively, these data show that filarial infections do stimulate immune responses; in some individuals these responses appear to be fully protective, but in others, immune responses contribute to the development of pathologic changes. This spectrum of responsiveness reflects a variety of patterns of Th cell and cytokine activity as well as parasite-induced immune suppression.

Analysis of protective responses to filarial nematodes has been carried out in vitro, using human cells and sera, and in vivo, using a variety of animal models. It has been shown in several cases that immunity can effectively operate through ADCC reactions directed against antigens present on the cuticular surface. The filarial cuticle is relatively delicate, compared with that of the intestinal nematodes for example, and may play a significant role in the uptake of nutrients. Antigens on the cuticle are known to be targets for antibodies, particularly IgG and IgE isotypes, and these facilitate adherence of cells such as eosinophils, macrophages, and neutrophils. Under experimental conditions, ADCC reactions can kill all stages, from microfilaria to adult; under conditions of natural infection it is most likely that a primary target is the incoming infective larva. Although the cuticle appears to be a major target for immune responses, other protective antigens have also been identified. Antigens derived from internal tissues, including muscle proteins, can elicit protective responses when used to immunize experimental animals.

Immunity to filaria is T-cell dependent and involves the activity of Th cells. In humans, putative immunity correlates with production of T-cell dependent antibody isotypes (IgE and IgG3), and these isotypes are also required for effective ADCC. Production of eosinophils, a contributor to cytotoxicity, is also T dependent. Studies in experimental animals have confirmed the need for Th cell activity, and shown that in some cases the Th2 subset is functionally important, IL-4 being a key cytokine (Lawrence 1996; Volkmann et al. 2001). There are some interesting exceptions to these conclusions (e.g. Le Goff et al. 2002) and these raise the perennial problem as to how representative of human responses are those measured in experimental animals. However, reduced IL-4 production is often found in heavily infected individuals but present in putative immunes. A factor complicating interpretation of immune responses to filarial worms is the demonstration that they harbor symbiotic *Wohlbachia* bacteria (Taylor 2002). These play an important role in worm development and fertility; if the bacteria are removed by antibiotic treatment worms may die. *Wohlbachia*, however, releases a lipopolysaccharide-like endotoxin that can affect both the nature of the immune response and the consequential immunopathological consequences.

Some of the most interesting data concerning immune responses to filarial infections in humans are those that attempt to correlate patient status with particular components of the immune system (Nutman 2001). It is now widely accepted that, both for lymphatic filariasis and onchocerciasis, there are individuals in populations in endemic areas who neither develop patent infections

nor show any signs of diseases, yet are immunologically positive in the sense of having antiparasite antibodies and antigen-specific T-cell activity. Such individuals are often referred to as 'endemic normals', although the use of this term is debatable. The fact that these individuals remain parasitologically negative despite exposure to infected vectors implies effective control of incoming infections and it is thought that this control operates against the infective larval stages. Experimental data from *Brugia* infections in cats, as well as data from rodent models, support this interpretation; indeed there is good evidence that irradiated infective larvae can induce an effective immunity when used as a vaccine and that this immunity is Th2-dependent (Bancroft et al. 1994).

The suggestion that some individuals do develop immunity to filarial infections raises the question of why the majority apparently do not, despite evidence for immune responses to the parasites. Those who show parasitological or pathological evidence of infection can be divided into a number of categories (Freedman 1998; Nutman 2001). In lymphatic filariasis, the extremes are patients who are microfilaremic and asymptomatic, and those who are microfilaria negative but show obstructive pathology. Another category shows atypical allergic hyper-responsiveness (tropical pulmonary eosinophilia). The lymphocytes of those with high microfilaremia often appear to be unresponsive to parasite antigens when tested in vitro (as is also the case with cells from patients with heavy skin burdens of the microfilaria of *Onchocerca*). There is evidence that altered T-cell-subset activity (including Tr cells) and cytokine production are contributory factors (Maizels et al. 1995; Satoguina et al. 2002; Steel and Nutman 2003) but released parasite products themselves can be directly immunosuppressive (Allen and MacDonald 1998; Pfaff et al. 2002). The existence of phosphorylcholine on filarial molecules is associated with altered immune responsiveness, mediated through IL-10 (Houston et al. 2000) and IL-10 is increasingly recognized as an important modulator of the antiparasite response leading to an altered balance between Th1 and Th2 activity. One consequence of this is the high levels of circulating antiworm IgG4 and IgE. These isotypes are found in both microfilaremic and elephantiasis patients but in the former, the ratio between the isotypes is biased to IgG4 and in the latter, the bias is towards IgE. The high levels of IgG4 may inhibit allergic responsiveness in the microfilaremic patients, whereas high IgE may promote pathological responses leading to obstructive pathology. IgE may, therefore, be important in protection against larval stages, through mediation of ADCC, but it may also contribute to immunopathology via hypersensitivity reactions to adult worms. Other IgG isotypes are low in microfilaremic individuals but more prominent in the elephantiasis group, in whom they may again contribute to pathology.

The T-cell anergy seen in patients heavily infected with lymphatic filarias or with *Onchocerca* appears similarly to be due to down-regulation of T-cell responsiveness by the cytokine IL-10 (Mahanty et al. 1997; Doetze et al. 2000). This is released from both Th2 cells, monocytes and macrophages, but predominantly the latter. Microfilaremic patients show high IL-10 production and low antigen-specific T-cell proliferation; symptomatic patients produce little IL-10 and their T cells proliferate well when exposed to parasite antigen. These results suggest that Th1 responses are somehow involved in antiparasite activity, which may be both beneficial, giving immunity against larvae, and harmful, via inflammatory responses to adult worms. IL-4 secretion appears to be linked with that of IL-5, lymphatic filariasis being characterized by high peripheral eosinophilia. In filarial infections there is, therefore, a complex, parasite-induced interplay between Th subsets that results in modulation of antibody and cellular responsiveness and determines both the parasitological and pathological outcomes of infection (Figure 4).

Immunity to flukes

Several species of digenean Platyhelminthes are parasitic in humans. They can be divided into four categories, based on their locations within the body:

1. the lung flukes (*Paragonimus*)
2. liver flukes (e.g. *Clonorchis*/*Opisthorchis*)
3. intestinal flukes (many genera)
4. blood flukes (*Schistosoma*).

Both lung and liver flukes can be highly pathogenic, with infections resulting in severe tissue damage (see Lung and liver flukes). Serological and cellular responses to these parasites are well described, but are not easily correlated with protective immunity. Little is known of immune responses to the human intestinal flukes, although infections of mice with *Echinostoma* have shown that an effective immunity can operate. The most intensively studied flukes are the schistosomes.

SCHISTOSOMES

Adult schistosomes live in the blood vessels of the host. Infections are initiated by penetration through the skin of larval stages that have developed in aquatic snails. To reach their final location, the larvae (schistosomula) migrate from the skin via the lungs to the liver, where they develop into mature male and female worms. These form permanent pairs, and then move to the mesenteric veins around the intestine or the vesical veins around the bladder. Once there, the worms can survive for prolonged periods (possibly years) during which time the female releases large numbers of eggs. These must leave the body and hatch in water so that larvae can find and

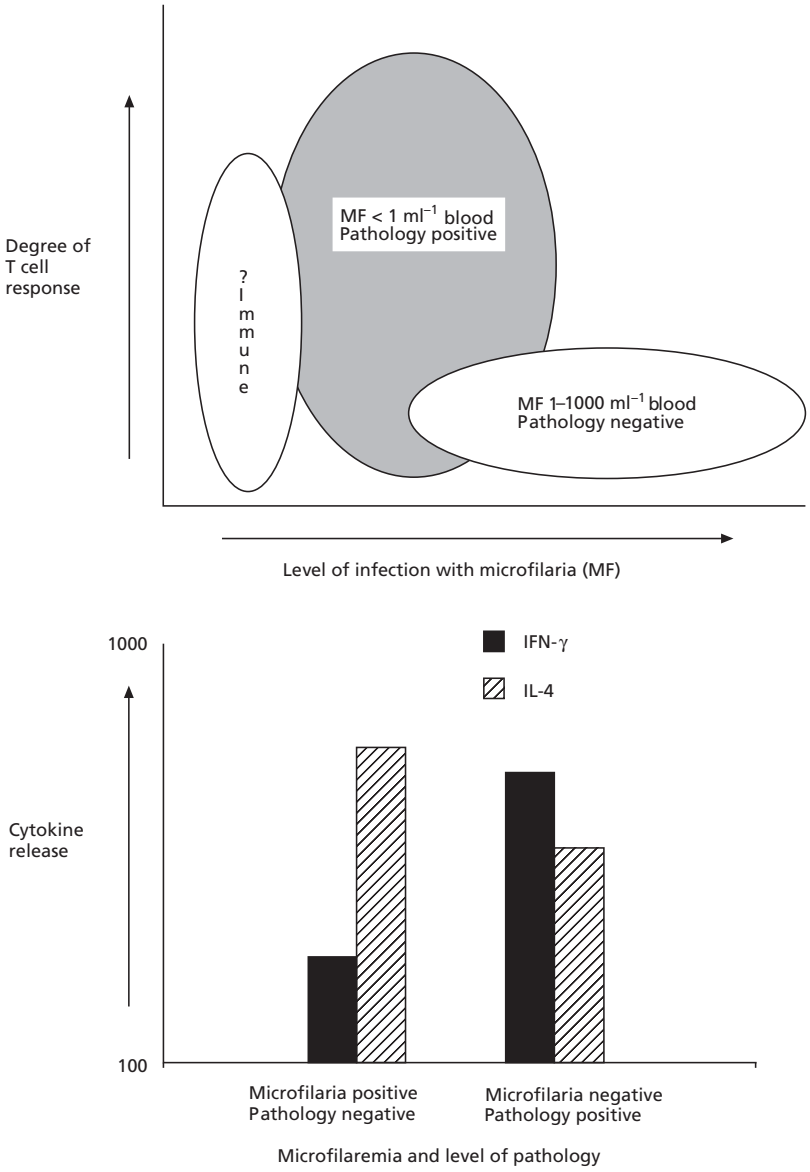

Figure 4 *Diagrammatic representation of the variations in T cell responsiveness and Th cell subset activity in patients infected with the lymphatic filaria* Brugia malayi. *T cell responses, reflected in level of proliferation when stimulated in vitro with antigen, are much higher in individuals without obvious infection (putatively immune) and in patients showing obstructive pathology than in those showing heavy microfilaremia but little pathology. Cytokine profiles, measured by in vitro cytokine production, indicate that heavy microfilaremia is associated with a predominant Th2 response (i.e. IL-4 production), whereas pathology in the absence of microfilaremia is associated with a predominant Th1 response (i.e. IFN-γ is the major cytokine). Data from Maizels et al. 1995*

penetrate a suitable snail. Eggs develop in the host's body and the contained larvae release enzymes that facilitate their passage out of blood vessels, through tissues into the lumen of the gut or bladder. Release from the body therefore occurs with feces or urine. There are three major species infecting humans: *Schistosoma japonicum*, *S. mansoni* (both in mesenteric veins), and *S. haematobium* (vesical veins).

Schistosomiasis is a multifaceted, immunopathological disease, but the most important components are the hypersensitivity responses initiated by eggs that are trapped in tissues (see Schistosomes: general). Granulomata form around the eggs, particularly those in the liver, and cause considerable local tissue damage. By blocking blood flow, granulomata can cause portal hypertension and serious vascular abnormalities, some of which (e.g. esophageal varices) may be life threatening.

Schistosome infections are common wherever climatic and environmental conditions favor snail development and where socioeconomic conditions allow fecal and urinary contamination of water that is used for drinking, bathing, washing or working. Infections are acquired early in life and are long-lasting; the disease is most

serious in older children and young adults. Initial infections appear to generate little or no protective immunity, but the intensity of infection declines with age and it is now accepted that this decline has an immunological as well as a behavioral component.

Experimental models have primarily used *S. mansoni*, which infects a variety of rodents and primates – work with other species is covered in Schistosomes: Asian. Primate studies defined the phenomenon of 'concomitant immunity' – the host is immune to reinfection while continuing to harbor the adult worms from an initial infection. Concomitant immunity was interpreted as showing that resistance mechanisms operated against the early schistosomula stage, but that adult worms were unaffected. In essence, this view still holds although there is now evidence that adults are also affected by immunity (Pearce and MacDonald 2002). Early studies also focused on effector mechanisms that resulted in damage to the tegumental surface which, in the larval stages at least, appeared vulnerable to direct damage by complement-mediated mechanisms and damage brought about by ADCC. The ability of adult worms (and indeed later larval stages) to survive in the face of responses capable of destroying early schistosomula depends on intrinsic changes in the tegument that render it less easily damaged, and the acquisition of host molecules (including glycolipids, immunoglobulin, and Fc receptors) that provide an immunological 'disguise'. In addition, schistosomes have a number of active evasion strategies that interfere with host immune mechanisms.

Experimental models, both in vivo and in vitro, indicate that there are multiple mechanisms through which resistance can be expressed. There is still no clear consensus about the mechanisms underlying protective immunity, although it seems clear that ADCC can be an important component of protective immunity. Several antibody isotypes and cell populations can participate in this response; eosinophils are major killer cells and IgG, IgE, and IgA are important isotypes. Interactions between parasites and macrophages may also be important, both in terms of ADCC and through the release of mediators capable of damaging the worms. A major difficulty, which has still to be resolved, is the relevance of data from animal experiments and from in vitro studies to the immune responses likely to occur in humans living in endemic areas (Capron 1998).

It is clear that schistosome infections elicit powerful CD4 T cell-dependent responses, the balance between Th1 and Th2 components being critical to the outcome (Hoffman et al. 2002). Data from experimental models show that the initial response is Th1 biased, switching to a Th2-biased response when egg laying begins. This switch is mediated by changes in local dendritic cells and co-stimulatory molecules as well as an altered cytokine environment in which IL-4 plays an important role (Gause et al. 2003) and is triggered by egg-associated carbohydrate antigens. These have specific glycan determinants that appear selectively to boost Th2 responses both to themselves and to bystander antigens (Okano et al. 2001). The antigens that can initiate protective immunity include molecules present at the surface of the tegument, the targets for ADCC as well as internal antigens. The latter include structural proteins, e.g. paramyosin, as well as a number with enzyme activity, e.g. glutathione S-transferase (GST) and triosephosphate isomerase. Several antigens have been defined and produced as recombinant or synthetic molecules and have been exploited as vaccine candidates (Bergquist et al. 2002). Trials have been carried out in rodents, bovines, and primates, with some degree of success achieved, largely in terms of reducing worm egg production and thus reducing egg-induced pathology. Clinical trials have been carried out using GST as the major antigen (Capron et al. 2001). However, not everyone is convinced about the need for and feasibility of a vaccine (Gryseels 2000) and this topic has been fiercely debated (Hagan et al. 2000).

The demonstration that immunity does play a part in determining the age-related decline in infection seen in endemic areas has come from detailed population surveys; these have monitored levels of reinfection after chemotherapy, as well as degrees of water contact. They have shown that individuals may effectively resist reinfection despite frequent contact with infected waters. Immunological studies on these populations have identified significant correlations between protective immunity and levels of antiworm IgE, but have also shown that other isotypes (particularly IgM, IgG2, and IgG4) can act as blocking antibodies and interfere with the expression of immunity (Hoffman et al. 2002). In young children (under 10 years) blocking antibodies predominate; in older children, protective IgE predominates. It is assumed that IgE may act in ADCC and that blocking antibodies interfere with the optimal operation of this protective mechanism.

Invasion and development of schistosomes are associated with distinct immunopathological phases. Penetration of the skin by cercariae causes a dermatitis, which may be severe in individuals sensitized by prior infection. The developmental stages may also be associated with allergic symptoms. This is particularly true in the case of *S. japonicum* infection in which fever, eosinophilia, lymphadenopathy, splenomegaly, and intestinal disturbances form the syndrome known as 'Katayama fever'. The hypersensitivity responses that lead to granuloma formation around trapped eggs have been studied in great detail, particularly in *S. mansoni* infections. Granuloma formation is the result of a complex series of cellular interactions involving T and B cells, antigen-presenting cells, eosinophils, and macrophages These interactions are coordinated through adhesion molecules, co-stimulatory molecules, chemokines, and cytokines (Sandor et al. 2003). Both Th1 and Th2 cells

contribute to granuloma formation, but down-regulation of Th2 activity occurs as infection progresses and this results in modulation of granuloma formation – IL-10 can play an important role in this process (Sadler et al. 2003). Granulomas eventually become surrounded by fibrous material, which helps to localize the lesion, but if excessive can lead to severe pathology. A balance between Th1 and Th2 responses appears to be critical: if either dominates, pathological levels of fibrosis may result. In the mouse, severe fibrosis appears to be Th2-mediated whereas in humans, a Th1 bias has been implicated (Fallon et al. 2000a; Hoffman et al. 2002; Pearce and MacDonald 2002), although IFN-γ has been associated with protection and TNF-α with aggravation of this disease (Henri et al. 2002). The severity of fibrosis in infected hosts is strongly influenced by genetic factors (Dessein et al. 1999).

S. mansoni and *S. japonicum* eggs leave the host's body via the intestine, which may become extensively damaged as tissues become sensitized to the eggs. Work in mice has shown that the enteropathy associated with this phase of infection is aggravated by Th2-dominated responses (Fallon et al. 2000b). In *S. haematobium*, the eggs of which leave via the bladder, inflammatory responses may produce severe pathological changes. There is a definite, but unexplained, association between such changes and the development of bladder cancers.

Immunity to tapeworms

Humans may act as hosts for adult stages of a number of tapeworm species. Some of these (e.g. *Taenia saginata* and *T. solium*) occur only in humans, others (e.g. *Diphyllobothrium latum*) occur in other hosts as well. Infections with adult tapeworms are acquired, in almost all cases, by ingestion of larval stages present in the bodies of intermediate hosts; for example, in the case of *T. saginata* by ingesting cysticerci present in infected beef and in the case of *D. latum* by ingesting plerocercoids present in infected fish. One species, *Hymenolepis nana*, has a unique life cycle in which development from the egg to the adult can take place within a single host. This species can, therefore, be locally quite common particularly in children. Very little is known of immune responses to adult tapeworms in humans; experimental studies with *H. nana* and other hymenolepids in rodents have shown that protective responses can act in the intestine against the adult stage.

LARVAL TAPEWORMS

In general, adult cestodes cause relatively little pathology, whereas larval tapeworms (metacestodes) can be highly pathogenic. In most cases, larvae are acquired by the accidental ingestion of eggs released from adult tapeworms in the intestines of other host species or from larval stages carried in transport hosts used for food. Larvae of the pork tapeworm *T. solium*, however, can develop from eggs released by adults in the intestine of the same or other humans.

The larval infections of greatest clinical importance are those caused by *T. solium* (cysticercosis), *Echinococcus granulosus* (hydatid disease), and *E. multilocularis* (alveolar echinococcosis) (see Larval cestodes). In all of these, the metacestodes formcyst-like structures in host tissues. Cysticercosis occurs wherever *T. solium* infections are common in the natural intermediate host, the pig. If infected pig meat is eaten raw or undercooked, the larval stages (cysticerci) become activated in the intestine, attach to the mucosa, and transform into the adult worm. When mature, the adult begins to shed segments (proglottids) that pass out with feces. As these decay, they release infective eggs that may contaminate water or vegetables, which then become a source of human infection. It is also thought that eggs can hatch directly in the intestine of a host harboring an adult worm (autoinfection). By whatever route infection is achieved, eggs hatch, then larvae penetrate the intestinal wall and migrate via the bloodstream. Cysticerci can form in the muscles, where they are relatively harmless, and in the central nervous system (CNS), where they can cause severe symptoms.

Larvae of *Echinococcus* spp. are acquired by accidental ingestion of eggs deposited in the feces of dogs or wild carnivores such as foxes. The eggs hatch in the small intestine, the larvae penetrate the mucosa and migrate via the blood, and develop in internal organs such as the lungs, liver, peritoneal cavity, and CNS. Larvae of *E. granulosus* grow into large fluid-filled cysts (hydatid cysts), whereas larvae of *E. multilocularis* form a pseudo-malignant mass of proliferating vesicular structures.

The immunological relationships between larval tapeworms and their hosts are complex and not well understood. Metacestodes often elicit little inflammation, they can persist for long periods and some can metastasize. All of these characteristics imply minimal or ineffective immune responses, yet it is quite clear that infections are immunogenic. There are many descriptions of cellular and serological responses to metacestodes in humans, from which some correlations with protective immunity can be drawn. There has been considerable work on infections in animal models, from which have come more precise insights into determinants of resistance and susceptibility. Immune responses can be considered as operative early or late in infection. The term 'early' describes responses against the hexacanth larva or onchosphere that is released from the egg and which undertakes the initial migration into the tissues; 'late' describes responses against the subsequent developing cystic metacestode stages.

In the early stages of larval development, the tapeworms have an unprotected external layer called the

tegument. They are, therefore, susceptible to damage by complement-fixing antibodies (e.g. IgG1 and IgG2 isotypes in mice; IgG2a in rats) and by complement- and antibody-mediated cellular cytotoxicity. Experimental studies show that host immunity can destroy larvae as they cross the mucosa or after they penetrate into other organs, but killing does not occur during an initial infection and the larvae become successfully established; early immunity is, therefore, most effective against reinfection. As the larvae develop, they acquire an external protective layer formed of both host and parasite components. They also produce sulfated polysaccharides and proteoglycans that interfere with host complement activation. In consequence, the larvae become insusceptible to the responses that can damage earlier life-cycle stages. Late immunity appears to operate exclusively through cytotoxic mechanisms, though these have little significant effect on larvae when they are fully developed. Larval tapeworm infections, like schistosome infections, therefore, show concomitant immunity, the host harboring fully developed primary infection larvae while being resistant to reinfection.

There is considerable evidence that larval tapeworms exert a variety of immunosuppressive effects on the host. For example, larval secretions (specifically glycoconjugates) inhibit T-cell proliferative responses and IL-2 production, prevent the accumulation of inflammatory cells, and interfere with normal macrophage functions (Dematteis et al. 2001; Rodriguez-Sosa et al. 2002). Infections, particularly with *E. granulosus*, generate powerful hypersensitivity responses, which can be life threatening if there is release of cyst fluid during surgical removal procedures.

Studies with *Echinococcus* spp. in experimental rodents and in humans are beginning to identify some of the key immunological events that may determine the outcome of infection (Gottstein and Felleisen 1995). As with many infections, there are striking genetically determined differences in the susceptibility and resistance of different strains of mice to this parasite. Mice that have greater resistance show responses that seem to indicate a dominant influence of Th1 cells, and the granulomata that develop around the mass of larval tissue contain a high proportion of CD8 T cells. In contrast, more susceptible mice, in which parasite growth is unchecked, have Th2-dominated responses and a high proportion of CD4 T cells in the granulomata. It is suggestive that similar data have come from studies of humans in endemic areas, some of whom, though susceptible to infection, seem to be resistant to disease. In these individuals, CD8 T cell numbers in the granulomata are high and peripheral lymphocytes secrete large amounts of the Th2 cytokine IL-5. Thus, Th1- and Th2-mediated mechanisms play a crucial role in the complex relationship between parasite and host (Vuitton 2003) and manipulation of the balance between the two may have clinical benefits (Godot et al. 2003).

There is no immediate prospect of immunoprophylaxis against larval tapeworm infections in humans, but the development of a recombinant vaccine against the larval stages of *Taenia ovis* in sheep has stimulated similar studies on vaccines against *Echinococcus* and *T. solium* cysticercosis (Lightowlers et al. 1996; Lightowlers 2003). Interestingly, one candidate antigen is paramyosin, also used in vaccine studies with schistosomes and filarial nematodes (Vazquez-Talavera et al. 2001). The most important practical application of immunological studies at present is the development of improved immunodiagnosis; larval tapeworm infections being difficult to diagnose definitively, even with modern scanning techniques.

In contrast to our current knowledge about immunity to intestinal nematodes, relatively little is known about responses to intestinal tapeworms. The human species (*Taenia*, *Diphyllobothrium*) appear to generate little or no protective immunity, although hosts do make immune responses (see Intestinal tapeworms). There is a considerable body of work using hymenolepid tapeworms in experimental rodents and this has given a significant body of data (Andreassen et al. 1999). Many aspects of the intestinal response in these models (e.g. mastocytosis, goblet cell hyperplasia, eosinophil infiltration, IgE) resemble those seen in nematodes (Ishih and Uchikawa 2000; Starke and Oaks 2001), but in the rat (the natural host) these are not linked to worm loss. In the mouse, this parasite is rejected and recent work shows that the mechanisms involved, as with nematodes in mice, are Th2-dependent (McKay and Khan 2003).

RESPONSES TO PARASITES MAY INTERACT WITH OTHER DISEASES

The powerful immune responses induced by parasites may be expected to influence the susceptibility of infected individuals to other diseases. It has been known for many years that the presence of one parasite may alter responses to a second, but in recent years there has been increased interest in broader aspects of parasite–disease interactions, in part triggered by the hygiene hypothesis. This states that early exposure to the antigens of infectious agents and environmental organisms can affect the balance of Th cell responses made subsequently, and thus influence susceptibility to allergic and autoimmune diseases (Rook 2000). Particular attention has been paid to the possible consequences of infections with intestinal helminths because of the ability of such infections to polarize towards Th2-dominated responses. It has been proposed that, because these worms are widespread in children in the developing world, they may be an important factor underlying the reduced prevalence of autoimmune and (paradoxically) allergic diseases in these regions (Cooper 2002) and there is some experimental evidence to

support this (e.g. Bashir et al. 2002). However, the position regarding the influence of parasites on autoimmune disease seem less clear cut (Agersberg et al. 2001). Evidence also suggests that infections with other worms such as schistosomes and *Onchocerca* can modulate responses to mycobacteria, responses to which are a powerful component of the hygiene hypothesis (Sewell et al. 2002; Stewart et al. 1999). Experimental data suggest that the strong Th2-biased responses associated with intestinal worms may alter susceptibility to autoimmune inflammatory diseases such as colitis and Crohn's disease (Elliot et al. 2000; Khan et al. 2002).

Worm infections have been associated with reduced responses to vaccines, although this may be more a reflection of an immune suppression (Cooper et al. 2001). They have also been linked to increased susceptibility to HIV and human T-cell lymphotropic virus (HTLV) infection, although the evidence here is sometimes contradictory (Ayash-Rashkovsky et al. 2002; Satoh et al. 2002; Wolday et al. 2002). A reciprocal effect of HIV infection and increased susceptibility to reinfection with *Schistosoma mansoni* has been described (Karanja et al. 2002). Recently, there has been interest in the interactions between intestinal worm infections and malaria. In endemic areas, where humans are commonly co-infected, epidemiological evidence has proposed both an increased incidence of *P. falciparum* and protection against cerebral malaria (Nacher et al. 2001, 2002).

The immune responses to infection with protozoa also influence infections with other infectious agents including viruses, bacteria, helminth worms, and other protozoa. There are numerous examples from experimental infections (see Cox 2001) but there is very little direct evidence that these interactions are important in humans, largely because of the difficulties inherent in carrying out the necessary definitive studies. The best-known example is Burkitt's lymphoma; the causative agent of this childhood lymphoma, the Epstein–Barr virus, is common all over the world but only causes tumors in areas where malaria is endemic (De The 1985) presumably as a consequence of malaria-induced immunodepression. There have been sporadic reports of enhanced bacterial infections in children infected with malaria (Walsh et al. 2000) and it has been known for some time that it is difficult to vaccinate children with malaria against tetanus, typhoid, or bacterial meningitis (Williamson and Greenwood, 1978). Acquired and innate immunodeficiencies also have an adverse outcome on infections with parasitic protozoa and the interactions between HIV and protozoa have been extensively studied. HIV infections are associated with enhanced *Toxoplasma gondii*, *Cryptosporidium parvum*, *Cyclospora cayetanensis*, *Isospora belli*, *Leishmania* spp., and *Trypanosoma cruzi* infections (see Ambroise-Thomas 2001). In all these cases, the parasitic infection is enhanced, and may even be fatal, in individuals infected with HIV. The most intensively studied interaction is the HIV/*Leishmania* combination, in which both organisms parasitize macrophages: HIV enhances the protozoan infection and vice versa, and the actual outcome of the dual infection is determined by a complex and changing balance between a number of different cytokines (Wolday et al. 1999). Interestingly there is very little evidence that HIV infections are enhanced in individuals infected with malaria although the reverse does seem to occur (Chandramohan and Greenwood 1998).

Our understanding of the Th1/Th2 dichotomy that has run as a thread throughout this chapter has opened up new prospects for the control of parasitic infections but it is clear that much more needs to be known about what happens in humans, particularly in those co-infected with another infectious agent, before any immunologically based preventative or therapeutic measures can be implemented.

Control of parasites, parasitic infections, and parasitic diseases

DAVID H. MOLYNEUX

Introduction and context	1	Stratification of parasitic diseases in relation to elimination and control	13
Concepts of control and eradication	6	Approaches to control	13
Public–private partnerships in disease control	8	References	28
Components of control	8		

INTRODUCTION AND CONTEXT

Since the publication of the 9th edition of Topley and Wilson in 1998, the landscape of global health has changed considerably. These changes have been driven by a series of initiatives that address broader development issues. These initiatives are as listed below.

1 Changed political awareness of international health issues with an increasing political commitment to poverty alleviation as a core component of agreed International Development Targets and Millennium Development Goals.
2 Changes in international organization policy and focus generated by changed leadership. In particular, the initiatives of the World Health Organization (WHO) in recognizing the need for public–private partnerships for health development; in defining priorities; and in launching initiatives such as Roll Back Malaria and the Tobacco-Free Initiative.
3 The establishment of the Global Fund for human immunodeficiency virus (HIV)/acquired immune deficieny syndrome (AIDS), tuberculosis (TB) and malaria following the initiative of the UN Secretary General. There is awareness that with the relentless problems of these diseases, even a fund of approximately US$2 billion will have limited impact since the estimated needs of HIV/AIDS, TB, and malaria come to an annual figure of c. US$10 - billion.
4 The new approach to donor-funding of health in poor countries where sector-wide approaches to financing (SWAP) (Cassels 1997) have been developed to enable a more coordinated approach to financing. This prevents donors from influencing, via special projects, the overall national health policy and plans. This so-called 'basket' funding recognizes that ownership rests with the country; that donors all contribute to the 'basket'; that, once committed, control of resources is lost; that priorities are established through policy dialogue; that partnership relations are strengthened. The SWAPs approach is also layered onto the increasing decentralization of national budgets to district-level management in many countries. However, the approaches of SWAPs to discourage project-specific or disease-specific funding appears at odds with the approaches of the Global Fund where disease-specific projects and programs are applied for.
5 Over recent years, large international nongovernmental development organizations (NGDO) have become increasingly active in disease control implementation and policy. Médecins Sans Frontières (MSF), Save the Children Fund (SCF), and Oxfam have been vociferous on issues of equity and access to drugs and in criticizing 'vertical' programs and drug donation programs. Notwithstanding policy papers introduced by NGDOs, MSF has advocated the establishment of a drugs for neglected disease initiative which, while necessary and laudable, must recog-

nize that in many circumstances such drugs require delivery through disease-specific methodologies and disease control is of necessity through approaches that are antipathetic to perceived policy wisdom of SWAPs and decentralization (e.g. trypanosomiasis or leishmaniasis).

6 There has been increasing recognition that infectious diseases are more prevalent and inflict a greater burden of disease on the poorest quintile of the population. The poorest 20 percent would benefit proportionately more if there was a pro-poor focus in tackling infectious diseases compared with other health interventions (Gwatkin et al. 1999).

7 There has been, in parallel with the recognition of the need for increased partnership, an expansion of public–private partnerships in health. These are summarized by Widdus (2001) who identifies some 70+ such initiatives. The diversity of objectives, financing, governance, and management of these alliances prevents any significant generalizations about best practice and how lessons can be learned as most of the alliances/partnerships are disease- or intervention-specific. The nature of some of these partnerships has been examined in more detail by Reich (2002), where some of the different models and experiences are discussed. Many of these have been developed over the past decade and have been funded by extensive long-term commitments from new donors, drug donations, long-term commitment from the private sector, and a recognition that relatively cheap interventions sustained by health systems can bring long-term health benefits. The establishment of the Bill and Melinda Gates Foundation as a key player in global health has greatly enhanced the opportunities for both research and intervention in parasitic infections. This Foundation, recognizing the importance of alliances that were embedded in its approach to program support, commissioned the study 'Building *Successful* Global Health Alliances', which outlines the parameters, criteria, and experiences of such alliances and creates a template through which to measure success (McKinsey 2002).

8 The introduction in 1993, following the World Development Report (World Bank 1993), of the concept of global burden of disease has been further expanded in a series of publications. Such data has enabled an assessment of likely change in global disease burden between 1990 and 2020. These projections suggest that as a proportion of global disease burden, only malaria remains a significant burden as a parasitic infection. Malaria falls in global burden importance from a ranking of 11th to a predicted 26th over this period. The majority of the projected changes in global burden are in the increased burden of cerebrovascular events, depressive illness, conflict-related conditions, road traffic accidents, and cancers. The disability-adjusted life years (DALY) burden of parasitic disease is projected to remain largely stable while the surge of noncommunicable disease burden due to the epidemiological transition, diet, and lifestyle change associated with urbanization, substance abuse, environmental degradation, population growth, and increased conflict are projected to be proportionally greater contributions. The DALY burden and overall public health importances of major parasitic disease are shown in Table 1.

9 The impact of nonhealth-sector roles, their financing and policies (e.g. education, agriculture, transport, natural resources) within government will have significant impact on health outcomes. Of particular importance will be levels of investment and achievement of education targets in an attempt to provide universal primary education by 2015; the importance of increasing the proportion of females in primary education will be of particular significance in achieving targets of improving maternal, child, and infant mortality figures. The complexities of the interactions and interrelationships are summarized in Figure 1

10 The interest in and, indeed, fear of emerging diseases (defined as either new infections of humans or re-emerging infections (where a rapid increase in incidence is seen of an existing infection or in a new geographical area) has been an important element in debate on health policy as epidemics of West Nile fever, Lyme disease, and Hantavirus have been recognized in the USA. Considerable additional resources have become available for research on such emerging agents. Recent quantitative analysis of the risk of emergence allied to the nature of the organism's mode of transmission and source have been provided by Taylor et al. (2001). They note that viruses, bacteria, and protozoa are more likely to emerge than macroparasites (e.g. helminths); that c. 75 percent of emergent organisms are from zoonotic sources and that emergences are independent of the mode of transmission. It should be noted, however, that despite the emphasis in some circles of the importance of such agents, they are not predicted to play a significant role in the global burden of disease estimates as a proportion of global DALYs. Such conclusions are based on the current definition of species. However, the capacity now exists to identify species complexes/groups and a level of intra-species variation is becoming apparent as a result of molecular analyses. The new discipline molecular epidemiology, which has been applied to vectors and causative parasites, clearly suggests that the absolute numbers of genetically distinct parasites and vectors, irrespective of subspecific variation, is much greater than hitherto recognized, emphasizing both the degree of biodiversity in microorganisms and its importance in the strategies of parasite and vector control.

Table 1 *Overview of public health importance of parasitic infection (see also Remme et al. 2002)*

Disease / Parasite	Population at risk (millions)	No. of endemic countries	No. of infected (millions)	Estimated deaths (humans × 1000)	DALYs female	DALYs male	Total DALYs
Malaria	2 000	90	300–500	1 080	182.3	17.5	357.3
Leishmaniasis	350	82	12	41	12	8.6	20.6
Lymphatic filariasis	750	65	119	No direct mortality	5.6	2.9	7.5
Guinea worm disease	140	18	c. 0.12	No direct mortality			
Onchocerciasis	122	34	17.6	No direct mortality	3.7	2.7	6.4
African trypanosomiasis	50	36	0.02–0.30	50	9	8.8	17.8
Chagas disease	90	19	16	21	14.8	12.6	27.4
Schistosomiasis	500–600	74	200	11	29.9	15.4	45.3
Ascaris infection			1 000		53.8	51.4	105.2
Trichuris infection			900		32.2	30.9	63.1
Hookworm infection			500		5.8	5.6	11.4
Entamoeba infection			500	40–100			
Giardiasis			200				
Taeniasis	40		15				
Neurocystocercosis			50	50			
Food-borne trematodes			500				
Fascioliasis	180.25	8	2.39				
Clonorchiasis	289.26	6	7				
Opisthorchiasis	63.60	5	10.30				
Paragonimiasis	194.80	5	20.60				
Other intestinal flukes		6	1.28				

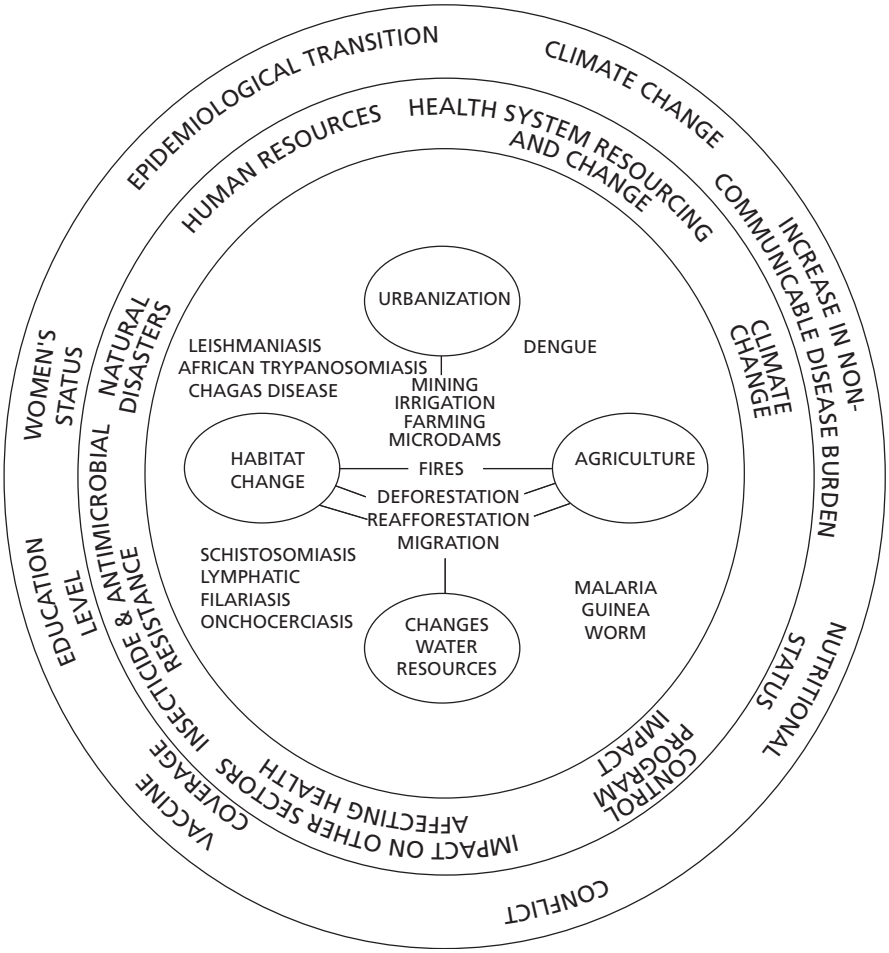

Figure 1 *Relationships and interactions between sectors intervention, environment, and vector-borne infection (Molyneux 2001)*

11 The suggestions that global climate change will have a widespread impact on health as mean temperatures rise over the next decades have provoked studies on the projected change in distribution of vector-borne infections. It is generally agreed (from different climate models) that the mean rise of temperature over the next 100 years will be of the order of 2–4°C. The impact of these changes, particularly on the distribution of *Plasmodium falciparum* malaria has been projected by various groups (IPCC 2001; Rogers and Randolph 2000; Hay et al. 2002; Patz et al. 2002) although little consensus is available (Patz et al., 2002). In addition, the role of El-Niño events has been studied and identified with changes in epidemic patterns in different regions of several vector-borne infections (dengue in Indonesia, malaria in most of Africa, Colombia, and India).

12 In many countries, the resources allocated to health remain disproportionately small compared with other sectors. The recent Macroeconomics and Health Report (WHO 2001) has made a significant contribution to the recognition that investment in health is critical to furtherance of human development and that significant returns on investment in health are obtained in the development process. Ill health is both a cause and consequence of poverty.

13 Civil unrest and disturbances, conflict and consequent migration, social disruption, and disruption of infrastructure including health services have had profound consequences for many populations over the last decade, particularly when associated with the end of the cold war. The impact of these events is summarized by Murray et al. (2002) and Supplement 1 to *Lancet* **360** (December 2002). The study of global burden of disease (Murray and Lopez 1996) suggests that the trend in disease burden associated with conflict will continue to rise to 2020. Molyneux (1997) summarized the impact of conflict on parasite infections; Table 2 updates available information on parasite infections in relation to conflict.

Epidemics may also be provoked by ecological, climatic, and environmental change; urbanization; human population movement resulting from civil unrest and conflict; reduced surveillance; and drug or insecticide resistance. Policymakers recommend that health systems are restructured to include a generalized 'horizontal' pattern of healthcare, insurance systems, and

Table 2 *Conflict related change in parasitic diseases*

Disease	Organism/location	Change
African trypanosomiasis (sleeping sickness)	*Trypanosoma brucei gambiense*	Epidemics in Democratic Republic of Congo (DRC) and Angloa over recent decades, associated with destruction/disruption of health services (Ekwanzala et al. 1996). Epidemics spread in north-western Uganda following conflict-related migration from Sudan.
	T. b. rhodesiense	Disruption of cotton and coffee production in Busoga during the Amin regime resulted in spread of *Lantana*, providing breeding sites for *Glossina fuscipes* and initiating transmission of acute sleeping sickness in peri-domestic environments, with cattle acting as reservoir hosts; restocking following cattle raiding induced epidemics following importations of infected cattle.
Visceral leishmaniasis	*Leishmania donovani*	Epidemics in southern Sudan: a changed ecological situation associated with an increase in *Phlebotomus orientalis* populations in maturing *Acacia / Balanites* woodland initially provoked the epidemics, which were left largely uncontrolled because of civil war, migration of infected populations, scarcity of treatment centers, and availability of drugs (Ashford and Thomson 1991; Seaman et al. 1992)
Cutaneous leishmaniasis	*Leishmania tropic*	Resurgence of *L. tropica* in Afghanistan (Kabul) following an increase in urban population density of non-immunes because of conflict (Ashford et al. 1992).
	Leishmania major	Movement of populations to Khartoum because of conflict and drought, and establishment of transmission among peri-urban reservoir of non-immunes living in shanties.
Malaria	Refugee camps in Africa	Refugee populations settled at lower altitude, in sites with relatively high rainfall; refugees with inadequate immunity or exposed to different strains of *Plasmodium falciparum*; absence of drugs and no control of *Anopheles gambiae*.
	Refugee camps in Afghanistan and Pakistan	Malaria epidemics in camps (controlled by spraying tents to control *A. stephensi* and *A. culicifacies*), exacerbated by increase in prevalence of *Plasmodium falciparum*.
	Cambodia	Mass deportation of urban non-immunes to forced labor in rice fields and forests; conscription for construction of defenses in border areas where multi-drug-resistant malaria commonly occurs.
Onchocerciasis	Sierra Leone	Weekly aerial larviciding against *Simulium* suspended because of security problems and local conflict. Levels of transmission consequently increased.
	Guinea Bissau, Sudan, Sierra Leone	Civil unrest prevented distribution of ivermectin with consequent resurgence in incidence.
	DRC, Central African Republic	Suspension or reduction of ivermectin distribution because of conflict.
	Liberia and Angola	Planning of program for community-directed distribution of ivermectin was retarded by collapse of national structures; remaining (passive) distribution by nongovernmental donors.
Dracunculiasis	Ghana	Increase in reported cases 1 year after local conflict failed to contain cases from previous year.
	Sudan	Civil war prevents adequate case-finding, case-containment, water-supply control, and filter distribution.

user charges, and decentralization of management to district level (or equivalent). Such restructuring reduces the ability of the system to respond to factors that lead to epidemics. It must be borne in mind that so called 'vertical' parasitic disease control activities (e.g. onchocerciasis control and the lymphatic filariasis, Chagas' disease, and Guinea worm eradication programs) have been remarkably successful, onchocerciasis control being judged particularly cost effective (Benton and Skinner 1990). Because of the complexity of the biological systems inherent in parasitic infections, particularly those that are vector-borne, such diseases are not easily amenable to control by a strictly 'horizontal' health system approach.

This chapter draws together information on the control of parasites, parasitic infections, and the diseases caused by parasites. The title distinguishes between the control of an organism (parasite, vector or ectoparasite) at the level of the individual and at the level of the community. An example of the paradox (individual vs. community) is the conflict between the treatment of individual patients compared with the need to control or even eradicate disease. It is important to emphasize these distinctions as they are frequently ignored by

policy makers, health workers, and scientists seeking to develop new approaches and tools for control.

The changing health environment has already been emphasized, but it is important to recognize that approaches to control are dependent on an accurate knowledge of the problem. This requires biological, medical, and epidemiological inputs to define the etiology (causative organisms), the vectors (if vector-borne), the parameters and mode of transmission (vector-borne, water-borne, aerosol, oro–fecal, venereal). Systems of surveillance, monitoring and evaluation are required to define prevalence and trends of infection and disease. Without such fundamental information, a control strategy cannot be appropriately designed and implemented. Biological information needs to be supplemented by consideration of issues such as:

- logistics
- cost-effectiveness
- potential for integration within existing programs
- past successes or failures
- input from governmental sectors other than health (e.g. agriculture, forestry, education, water, other natural resources, wildlife)
- acceptability of an intervention to the target communities
- potential for ecological damage
- priority rating afforded by the Ministry of Health (MOH)
- availability of human resources for implementation
- potential of research to provide improved products within a particular timescale.

The overall framework of approaches towards parasitic disease control is summarized in Figure 2.

CONCEPTS OF CONTROL AND ERADICATION

A distinction must be maintained between the terms 'control' and 'eradication'; the latter is often used inappropriately and it should be employed with caution. In 1988, the International Task Force for Disease Eradication (ITFDE) was formed to evaluate systematically the potential for eradication of candidate diseases and to identify specific barriers to eradication. The criteria used to asses the feasibility of eradication are provided in

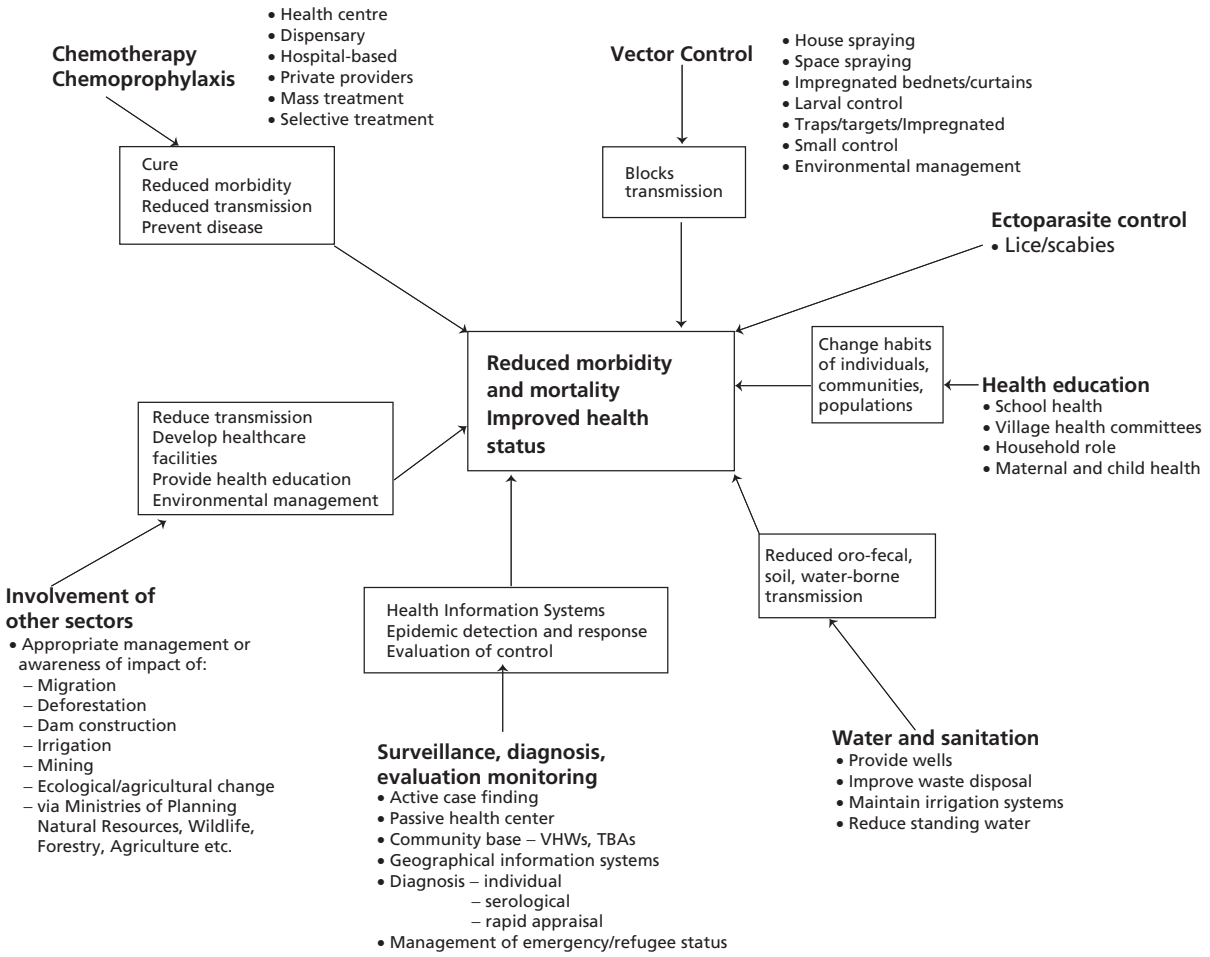

Figure 2 *Framework for the control of parasitic diseases*

Table 3 *Criteria for assessing eradicability of diseases or conditions (Dowdle and Hopkins 1998)*

General category	Specific criteria	Examples
Scientific feasibility	Epidemiologic vulnerability	Existence of nonhuman reservoir; ease of spread; natural cyclical decline in prevalence; naturally induced immunity; ease of diagnosis; and duration of any relapse potential.
	Effective, practical intervention available	Vaccine or other primary preventive, curative treatment, and means of eliminating vector. Ideally, intervention should be effective, safe, inexpensive, long lasting, and easily deployed.
	Demonstrated feasibility of elimination	Documented elimination from island or other geographic unit.
Political will / Popular support	Perceived burden of the disease	Extent, deaths, other effects; true burden may not be perceived; the reverse of benefits expected to accrue from eradication; relevance to rich and poor countries.
	Expected cost of elimination or eradication	Especially in relation to perceived burden from the disease.
	Synergy of eradication efforts with other interventions	Potential for added benefits or savings or spin off effects.
	Necessity for elimination rather than control.	

Table 3. The ITFDE has recently been reconstituted to evaluate the present situation as new developments have taken place over the last decade. The ITFDE defined eradication as 'reduction of the worldwide incidence of a disease to zero as a result of deliberate efforts obviating the necessity for further control measures.' The original ITFDE reviewed more than 90 diseases, 30 of them in depth, and concluded that dracunculiasis, rubella, poliomyelitis, mumps, lymphatic filariasis, and cysticercosis could probably be eradicated using existing technology. The term 'elimination' is increasingly being used to replace the term 'eradication,' which should be only used in a global context. The Dahlem conference held in Berlin in 1997 (Dowdle and Hopkins 1998; WHO 1998) also considered these issues in some detail and introduced the term 'extinction' to classify an organism that no longer exists (in contrast to the causative organism of smallpox, which has been eradicated as a cause of disease but still exists in stocks retained in secure laboratories). 'Elimination' is now regarded as meaning removal of an organism from a defined geographical region (local eradication) which creates problems for quantification of achievement towards the goal. The accepted position is that the disease is not eradicated but no longer requires ongoing investment in control and is maintained at a level where the problem is no longer a significant health burden. A new concept, 'elimination of a disease as a public health problem' has been introduced through World Assembly Resolutions. The definitions used in this chapter are from Dowdle and Hopkins (1998) and are as follows:

- Control: Reduction of disease incidence, prevalence, morbidity or mortality to a locally acceptable level as a result of deliberate efforts; continued intervention measures are required to maintain the reduction.
- Elimination of disease: Reduction to zero of the incidence of a specified disease in a defined geographical area as a result of deliberate efforts; continued intervention measures are required.
- Elimination of infection: Reduction to zero of the incidence of infection caused by a specified agent in a defined geographical area as a result of deliberate efforts; continued measures to prevent re-establishment of transmission are required.
- Eradication: Permanent reduction to zero of the worldwide incidence of infection caused by a specific agent as a result of deliberate efforts; intervention measures are no longer needed.
- Extinction: The specific infectious agent no longer exists in nature or the laboratory

The classic eradication program was that of smallpox, which achieved its target in 1977. To date, no parasitic disease has been eradicated, although attempts to eradicate Guinea worm are underway, through the program Global 2000 (Hopkins et al. 2002). Nevertheless, successful local eradication (correctly, elimination) has been achieved in some restricted geographical or epidemiological situations:

- onchocerciasis has been eliminated from several parts of Kenya and from the Nile at Jinja in Uganda by using the insecticide dichlorodiphenyltrichloroethane (DDT) to remove the local vectors (*Simulium neavei* and *S. damnosum*, respectively)
- the Onchocerciasis Control Programme (OCP) in West Africa has achieved the same goal by targeting particular cytoforms of the *S. damnosum* complex using aerial application of insecticides.

Local elimination has also been achieved as detailed below:

- the malaria vector *Anopheles gambiae* from Brazil in the late 1930s by Soper using larviciding measures and house spraying with pyrethrum, a success repeated in the early 1940s after the same species had been introduced into Egypt
- *Glossina palpalis*, the tsetse fly, the vector of human trypanosomiasis was eliminated from the island of Principe in 1905 by trapping flies using sticky back packs on plantation workers
- animal trypanosomiasis has been eliminated from parts of North East Nigeria by ground spraying of tsetse resting sites with persistent doses of DDT
- *Aedes aegypti*, the vector of yellow fever, has been eliminated from parts of Central and South America
- local antimosquito spraying has eliminated lymphatic filariasis from the Solomon Islands with no evidence of any resurgence over a 20-year period
- filariasis due to *Brugia malayi* has been eliminated from Sri Lanka through selective treatment with the drug diethylcarbamazine (DEC), antilarval measures (removal of host plants by herbiciding) and environmental improvements
- chemotherapeutic approaches have eliminated filariasis due to *Wuchereria bancrofti* from Japan, South Korea, and Taiwan in Asia, and Suriname and Trinidad and Tobago in the Americas (WHO 1994)
- filariasis has also been eliminated as a public health problem in large areas of China
- a long-term 'elimination' program has been successful against hydatid disease in Iceland
- malaria was eliminated from Sardinia by DDT spraying as well as in other marginal areas of distribution.

One noticeable feature of these successes is that many examples refer to islands or isolated populations or areas where the parasite is at the edge of its geographical range. Clearly, the advantages of isolation and a greater ability to control animal or human population movements are important. Elimination or global eradication of any disease is difficult to achieve and costs increase per case detected, controlled or averted as the end-point is reached.

However, the high cost of eradication or local elimination programs may be justified as these costs are time limited, whereas disease control implies a long-term commitment. Any control program must be cost-effective and should reduce the target disease to a level at which costs are sustainable by the local community (or by public or private healthcare systems). Control seeks to bring the problems to a level at which the disease is no longer of public health importance with morbidity at an acceptable level within the community, an absence of mortality and, if appropriate, greatly reduced levels of disability. To translate the level of control achieved to eradication or elimination status requires *either* a vastly increased cost per case treated or prevented which, for financial and ecological reasons, may never be feasible, *or* the development of a more effective intervention.

PUBLIC–PRIVATE PARTNERSHIPS IN DISEASE CONTROL

There have been significant developments of public–pri-private partnerships (PPP) for disease control over recent years. These have, in part, been generated by the new policies of the Director-General of WHO, Dr. Gro-Harlem Brundtland, following her election in 1998 but also by the recognition that such partnerships represent a response to the changing environment in international health and that no single organization can undertake or be responsible for all aspects of health and its delivery. Recent PPPs in parasite control include:

- African Programme for Onchocerciasis Control (APOC)
- OCP (1974–2002)
- Onchocerciasis Elimination Programme in the Americas (OEPA)
- Roll Back Malaria
- Multilateral Initiative on Malaria
- Medicines for Malaria Venture
- Global Allliance to Eliminate Lymphatic Filariasis
- Global School Health Initiative
- Partnership for Parasite Control
- Global Alliance for African Human Trypanosomiasis
- Guinea Worm Eradication Programme (also known as 'Global 2000').

Each of these PPPs has different characteristics (e.g. governance, financing, time frame, links with the private sector) and different disease-specific objectives. Widdus (2001), Buse and Walt (2000a, b), Reich (2002) and Buse and Waxman (2001) provide a detailed analysis of the underlying principles of these alliances as well as case studies of functionality.

COMPONENTS OF CONTROL

Components of control are listed under the following headings:

- Situation analysis
- Definition of objectives and strategy
- Options and responsibilities at different levels of health system
- Planning and resourcing
- Evaluation and monitoring
- Implementation and integration of selected methods of control.

Situation analysis

- Perform desk study of published and unpublished reports to assess problems in the context of country, region, and district.

- Acquire information on prevalence and incidence.
- Appraise the validity of information.
- Evaluate current epidemiological situation by passive surveillance at health centers or by questionnaires (e.g. using the postal system).
- Observe changes over time and predict future change.
- Define the structure of health services and their existing capacity, human resources available, and needs for training and capacity building.
- Establish the priority afforded to the disease by the government, the MOH, the district management teams, and the communities.
- Establish links to other sectors or organizations in planning for control (e.g. other ministries, development organizations, nongovernmental organizations (NGO).
- Assess the influence of other activities such as development projects on planned programs.
- Carry out spot surveillance of local prevalence, vectors and, if applicable, animal reservoirs.
- Use rapid assessment methodologies (e.g. for schistosomiasis, onchocerciasis, filariasis, or loiasis).
- Assess the available methods for prediction of epidemics using remote sensing or climate prediction available to other sectors (e.g. agriculture, natural resources, environment).
- Establish a national task force composed of various stakeholder groups to address the problem.

Definition of objectives and strategy/options and responsibilities at different levels of health system

- Analyse cost-effectiveness of different control approaches and options.
- Select appropriate methodology and define control requirements.
- Establish an inventory of personnel and facilities (including estimation of training needs and requirements for equipment and drugs).
- Establish feasibility in the context of other health needs.
- Contrast epidemic ('firefighting') problems for which vertical, rapid intervention is necessary with endemic situations for which a long-term approach and integration are required (Table 4).
- Establish emergency response capacity to address predicted epidemic risk.

Planning and resourcing

- Define the expected contribution from the government.
- Develop national plan.
- Evaluate targeted approaches to donors in the context of donor priorities and prevailing national policy.
- Define appropriate timeframes for implementation of plans.

Table 4 *Role of different levels of the health system in parasitic disease control*

Level	Role
Community	Identification of suspects/patients
	Follow-up of patients
	Coordination of any appropriate vector-control activities (e.g. bednet distribution to vulnerable groups/reimpregnation)
	Facilitation of cooperation, local logistics
	Communication by village health committees
District	Passive detection and treatment
	Parasitological/serological diagnosis
	Treatment and minimum clinical care
	Follow-up of microscopy
Regional	Active surveillance
	Confirmatory diagnosis
	Data collection
	Technical supervision of vector control
	Distribution of reagents and materials for vector control
Ministry/country level	Situation analysis/policy position
	National strategy and plan
	Establish stakeholder group/national task force
	Financing
	Training needs and responsibility
	Health education
	Distribution of technical information, equipment, drugs, materials
	Purchase of equipment and supplies
	Human resource management

- Define the relationship of the action to overall health plans and budgets.
- Establish links with appropriate international reference centers for technical support; control of an epidemic may merit application for emergency status to provide rapid funding (e.g. requests for therapeutic drugs and insecticides from international aid agencies and NGDOs).
- Establish drug supply line following identification of sources; initiate quality assurance mechanisms; define tax status of drugs (e.g. donated products).
- Define role of the nongovernment sector (e.g. private providers, NGOs) in control policy.
- Ensure adequate information exchange about control policy between different bodies and individuals involved.
- Undertake knowledge, attitudes, and practice (KAP) studies as a basis to inform approaches to social mobilization strategies.
- Train personnel (including management) through courses, instruction of trainers, educational materials, and health education programs.
- Assess community acceptability and the perceived priority of any involvement that will require resource input from the communities (e.g. role and views of village health workers (VHW), volunteers, traditional birth attendants (TBA), community leaders, school teachers).
- Define the management structure of the program and its relationship with existing management structures.
- Assess capacity available (managerial, financial, technical) and ensure capacity building is embedded in planning.

Evaluation and monitoring

- Assess progress towards objectives (prevalence distribution, vector status).
- Establish sentinel site / baseline data in defined units.
- Define appropriate methods for epidemiological evaluation, e.g. parasitological, serological, and vector sampling methods.
- Carry out longitudinal surveys or spot surveys at indicator villages.
- Adjust the program in the light of results.
- Establish process indicators at national and subnational level.

Examples of the value of assessing longitudinal trends in disease control are illustrated in Figures 3a–e, 4a, b, p. 14, and 5, p. 15. These show trends in parameters that measure the impact of implementation of selected methods of control on onchocerciasis, Chagas' disease, and Guinea worm either by measures that indicate change of incidence or by directly measuring vector populations and hence transmission since the program began.

Implementation and integration of selected methods of control

CHEMOTHERAPY AND CHEMOPROPHYLAXIS

- Assess the availability and quality of drugs and the distribution system.
- Establish relationship between national bodies, donation programs, and NGDO community to define operational relationships (e.g. onchocerciasis, lymphatic filariasis, African trypanosomiasis, schistosomiasis, trachoma programs).
- Assess or monitor drug resistance (e.g. East African network for antimalarial drug resistance).
- Assess the role of private providers and control of quality and price (e.g. malaria drug policy).
- Utilize other systems for distribution (e.g. schools, agricultural extension workers, other health or government workers, NGOs, committees).

VECTOR AND RESERVOIR CONTROL

- Assess availability, cost, and appropriateness of insecticides.
- Assess availability of skills to monitor insecticide resistance.
- Assess availability and effectiveness of alternative chemicals.
- Assess capacity for management of the control program.
- Establish relationships with other sectors to provide support for environmental control measures.
- Assess acceptability and feasibility of reservoir control.
- Assess environmental acceptability of interventions.
- Assess personal protection (e.g. bednets, sustainability of a bednet program/retreatment modalities).
- Establish policy in relation to bednet distribution (e.g. vulnerable groups, social marketing).
- Investigate opportunities for integration if appropriate (e.g. malaria and lymphatic filariasis in Africa; dengue and filariasis in the Pacific; leishmaniasis, Chagas' disease, and malaria via bednets in Latin America).

ENVIRONMENTAL MANAGEMENT

- Ensure effective linkages between health and other sectors.
- Assess potential impact on other diseases.

IMMUNOPROPHYLAXIS

- Assess availability of vaccines.
- Assess capacity to manage the program and efficacy of cold chain.

Note the extensive distribution in areas formerly in extension areas with 'core area' free of onchocerciasis except in restricted area.*

- Establish links to existing programs (e.g. expanded program of immunization (EPI) to utilize the cold chain).

HEALTH EDUCATION / SOCIAL MOBILIZATION

- Use media resources, including radio, television, and video.
- Use posters and drama sessions oriented around the local environment and traditions.
- Ensure participation of teachers, local leaders, health workers, local medical practitioners, religious leaders.
- Ensure link to KAP and feedback to inform social mobilization strategy.

STRATIFICATION OF PARASITIC DISEASES IN RELATION TO ELIMINATION AND CONTROL

Control programs often involve specific approaches to arrest the transmission of infection (e.g. via vector control) or to prevent or cure a disease. Although such programs have been successful in the past, integrated approaches are now recognized as being more appropriate for reducing prevalence and incidence. This is important if the strategy is aimed at alleviation of a disease problem in a community or population rather than in an individual. Integrated control is based on coordinated planning and detailed knowledge from many different areas: scientific, technical, intersectoral, financing, and managerial. An approach termed 'stratification' has been used in malaria control; it means that the strategy is modified according to different epidemiological situations (WHO 1993a). Malaria stratification has been taken a step further by those with particular interests in different environments and geographical regions, a process known as 'micro-stratification' (Rubio-Palis and Zimmerman 1997). While stratification has been most widely discussed with reference to malaria (Table 5, p. 29), the process is equally applicable to other parasitic diseases: leishmaniasis (WHO 1990), onchocerciasis, filariasis (WHO 1992a), schistosomiasis, and African trypanosomiasis. Tables 5–10, p. 29–39 illustrate the concept of stratification in the planning of control in selected parasitic diseases.

APPROACHES TO CONTROL

Control of a parasitic infection can be focused on the individual, with a view to alleviating pain, reducing disability or avoiding death, while at the same time reducing the parasite load and transmission within a community. Such an approach will be less cost-effective than larger-scale control programs that employ methods such as vector control, reservoir-host control or mass drug distribution. Large-scale measures have a public health objective that, while reducing individual suffering, also reduces community morbidity and mortality. This

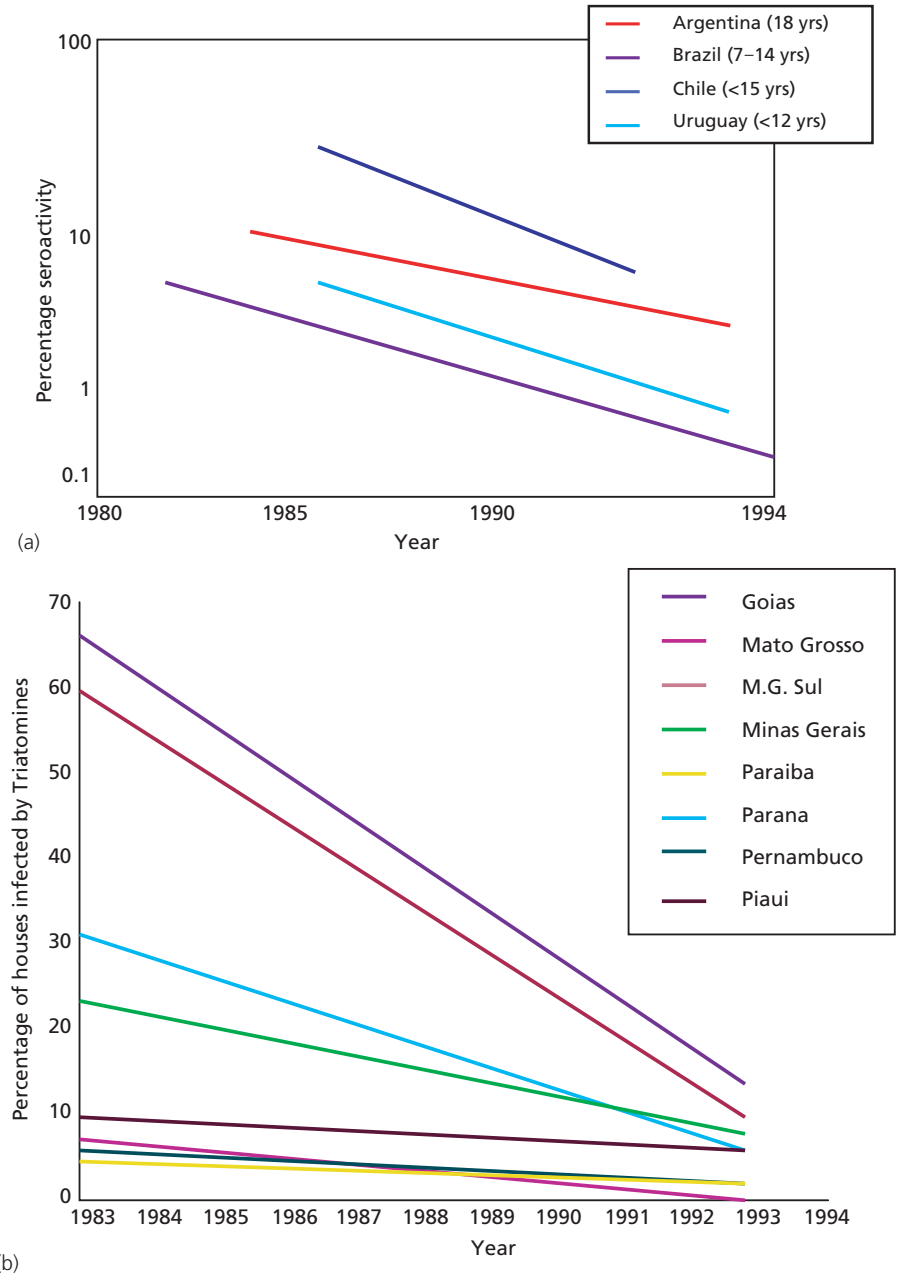

Figure 4 *Southern Cone Initiative.* **(a)** *Elimination of transmission: incidence of Chagas disease 1980–94 (Moncayo 1999).* **(b)** *Interruption of transmission: Brazil, endemic states 1983–93 (Gadelha 1993).*

provides socioeconomic benefits through improved agricultural productivity, improved cognitive function, better nutrition as a result of increased agricultural output of a more varied diet, and enhanced population mobility allowing for additional earning opportunities. Control of animal parasitic diseases also has benefits for human populations through increased protein availability and higher income from the sale of higher-quality livestock enhancing both local and national economies. Parasitic disease control programs vary in scale but they have generally been targeted at two different types of disease situation:

1. endemic disease in which long-term chronic infections have persisted in communities (e.g. onchocerciasis, hydatid disease (*Echinococcus* infection), schistosomiasis, Guinea worm (dracunculiasis), Chagas disease, and filariasis
2. epidemic disease where rapid intervention is required to prevent widespread morbidity and mortality.

Epidemics are frequently predictable but if health facilities are ill-equipped or nonexistent, high mortality may occur before control can be instigated. Recent examples of parasitic disease epidemics are described in Table 11, p. 40.

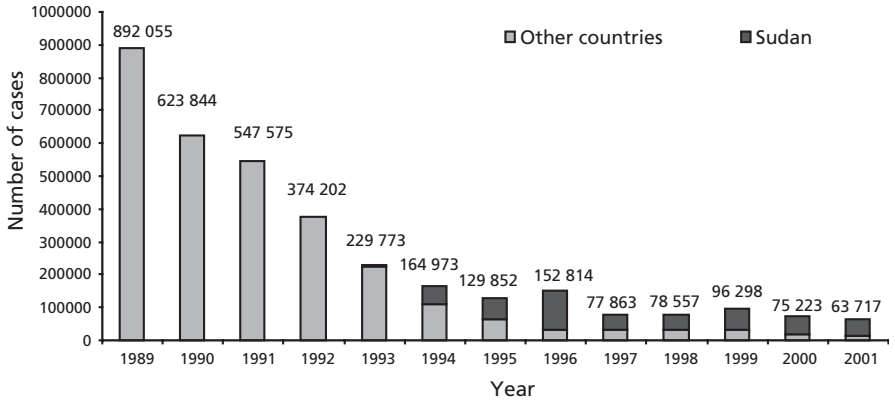

Figure 5 *Declining trend in dracunculiasis prevalence 1989–2001 (WHO 2002b)*

Anthropogenic and environmental changes frequently result in epidemics of parasitic disease. Several reviews have identified the primary drivers of these changes (Molyneux 1997, 2003a, b) as listed below:

- Movements of non-immune populations in areas where transmission occurs. Such movements may be of an organized nature (e.g. mobilization of the workforce in Brazil to exploit forest resources has resulted in malaria epidemics). Alternatively, they may occur without formal organization (e.g. movements of workers involved in mining for gold or gems in the Amazon and South East Asia).
- Climatic changes (e.g. temperature change is considered to be a cause of highland malaria in Kenya and Ethiopia). Unusual levels of rainfall following periods of drought result in epidemics of malaria in East and South Africa.
- Urbanization results in populations being exposed to new organisms as vectors establish in new habitats and peridomestic reservoirs act as sources of infection. Health services are grossly inadequate or nonexistent and service providers are often only NGDOs or faith groups. The increasing impact of urbanization on various different forms of leishmaniasis has been highlighted by WHO (2002a): for zoonotic cutaneous leishmaniasis (*L. guyanensis* and *L. brasiliensis*) in Brazil, Colombia, and Venezuela; for anthroponotic cutaneous leishmaniasis (*L. tropica*) in cities of south west Asia (Afghanistan, Iran, Syria, and Iraq); for zoonotic visceral disease (*L. infantumi*) in north-east Brazil where drought-induced migration to cities in which peri-urban shanty settlements provide conditions for transmission between humans and dog reservoirs via *Lu. longipalpis*.
- Changes in vegetation such as the development in Uganda of thickets of *Lantana*, which provided a habitat for *Glossina fuscipes* thus provoking epidemics of Rhodesian sleeping sickness. Another example is deforestation, which has resulted in exposure to leishmaniasis in the Amazon (Walsh et al. 1993).
- Development projects, particularly those involving water resource development, frequently exacerbate the health problems of the local or incoming population (Birley 1995; Hunter et al. 1993).
- Conflict, civil unrest, and associated population disruption have profound impacts on parasitic diseases and epidemics are frequently associated with such events. Disease-causing organisms with a capacity for rapid adaptation and reproduction that are associated with vectors having characteristics as generalists are more prone to create health problemsin conflict environments (Molyneux 1997). Tables 2 and 15, p. 43, summarize recent examples of changes in parasitic-disease epidemiology associated with conflict and characteristics of generalist vectors.
- Agricultural development projects, particularly those linked to irrigated agriculture and development of monocultures are associated with changed patterns ofinsect-borne infection, especially malaria (Ijumba and Lindsay 2001), Japanese encephalitis, leishmaniasis.

Common themes which operate in the above settings and are associated with changing vector-borne diseases include:

- epidemics associated with generalist vectors (characteristics of generalist vectors are listed below)
- animal reservoirs or mixing vessels associated as food sources with generalist vectors
- animal reservoirs that may be domestic, wild or intensively reared
- reduced biodiversity (often associated with the impact of hydrological change and deforestation/reforestation), which encourages expansion of adaptable generalist vectors and reservoirs
- ratio of *P. vivax*: *P. falciparum* changing with increasing *P. falciparum* (see also Table 15, p. 43)
- extractive activities (uncontrolled) generating the development of antimalaria resistance

- hydrological impacts over variable time-frames
  malaria and Japanese encephalitis – acute
  schistosomiasis / dracunculiasis – medium
  filariasis – chronic
- deforestation/reforestation impacts via
  behavior of humans, animal reservoirs, and vectors
  edge/interface effects/fragmentation patterns
  degree and type of reforestation
  loss of biodiversity
  loss of forest causing elimination of vector species
  common pattern of change occurring within different vector complexes.

Characteristics of generalist vectors include:

- wide geographical distribution
- species complexes or species groups
- capacity to feed on a range of available hosts
- ability to exploit peridomestic and peri-urban settings
- abiltiy to exploit new pre-imaginal habitats
- efficient vectors with high vectoral capacity
- no transovarial transmission.

Control of animal reservoir hosts

Many parasitic diseases are zoonoses, defined as 'those diseases and infections (the agents of) which are naturally transmitted between (other) vertebrate animals and man' (WHO, 1979). A list of recognized parasitic zoonoses is provided by the WHO (1979). Ostfeld and Keesing (2000) provide an updated list of vector-borne infections of potential public health importance, while a recent analysis of all emergent and re-emergent infections (Taylor et al. 2001) has identified that 75 percent of emerging pathogens are zoonotic and that such organisms are more than twice as likely to emerge as nonzoonotic ones. However, viruses and protozoa are more likely to emerge than macroparasites such as the helminths. The important zoonoses for which reservoir control can have a cost-effective impact are discussed below. The presence of an animal reservoir host may be a major impediment to control of a disease, particularly if the habits and habitats of the animal hosts prevent intervention either on the grounds of practicality or for reasons such as protected status of the host (e.g. primates or endangered species). The International Commission for Disease Eradication recognizes that the existence of a reservoir host precludes the likelihood of eradication or elimination of the infection (see Table 3).

LEISHMANIASIS

Among the most important examples of control programs targeted against animal reservoir hosts was that aimed at the great gerbil *Rhombomys opimus*, the reservoir host of *Leishmania major* in the former Soviet Union; a variety of techniques were employed to eliminate this rodent in the central Asian republics of Uzbekistan, Kazakhstan, and Turkmenia. Burrow systems identified by aerial or ground surveys were destroyed by deep plowing. Alternatively, poisonous baits of zinc phosphide mixed with wheat and vegetable oil were introduced into every third or fourth hole. The effects of the zinc phosphide were enhanced by prior application of the anticoagulant, dicoumuarol, 5–7 days earlier. Because of its high toxicity, zinc phosphide had to be inserted directly into the rodent burrows. Elimination of *R. opimus* can also be achieved by flooding burrows in irrigation schemes. Reinvasion can be prevented by canal construction and agricultural development.

The fat sand rat *Psammomys obesus* (reservoir of *L. major* in the Near East and North Africa) has not been effectively controlled as it is not granivorous and because anticoagulants are too expensive for large-scale use. The other reservoir hosts of *L. major* (*Meriones* spp. and *Tatera* spp.) are not easily controlled. Large-scale control of hyraxes (reservoirs of *L. aethiopica*) needs to be organized at a local level using shooting and trapping.

The animal reservoirs of visceral leishmaniasis (*L. infantum* and *L. i. chagasi*) are domestic and wild canids. The instigation of dog control for rabies control in China has reportedly reduced the incidence of visceral leishmaniasis to almost zero. Elimination of stray dogs is justified for many reasons and although shooting and poisoning are effective they are not acceptable to some communities. In some countries (e.g. France) screening of domestic dogs for *Leishmania* spp. by serological examination in parallel with clinical examination, permits infected animals to be identified and either destroyed or treated. Treatment is not, however, entirely effective and an alternative approach is to administer a single prophylactic treatment shortly before the peak transmission season. Control of canine leishmaniasis could be integrated with rabies control by:

- registration of dogs
- regular evaluation and surveillance
- serological diagnosis
- mobilization and motivation of the dog-owning community.

However, a new approach has been the use of insecticide (deltamethrin)-impregnated collars on domestic dogs; this reduced the proportion of sandflies that took blood meals and survived by over 90 percent for at least 8 months after collars were applied (Killick-Kendrick et al. 1997). The importance of controlling canine leishmaniasis is underlined by the finding that human *L. infantum* infection is more widespread in southern Europe than was previously thought and by the fact that visceral leishmaniasis is an HIV-associated disease. In South America, and to a lesser extent in Europe, the presence of wild canid reservoirs necessitates a continuous commitment to control.

There is limited opportunity to control the wide range of reservoir hosts of New World cutaneous leishmaniasis. The WHO (1990) suggests that control of the opossum (*Didelphis marsupialis*) could be achieved by using baited pitfall traps in urban and peri-urban environments or in disturbed primary forest; this would result in control of *L. guyanensis*. *T. cruzi* might also be tackled by the same measures in peri-urban situations, but the cost-effectiveness of such measures remains to be validated. The WHO suggests an environmental management approach combining primary forest clearance with insecticide application, in order to create a vector-free and reservoir-free zone around villages. The transmission of *L. guyanensis* has been greatly reduced by these measures in French Guyana.

HYDATID DISEASE

Dogs and other canids are the definitive hosts of *Echinococcus granulosus*. Several countries have instigated dog control and surveillance and chemotherapeutic treatment (with praziquantel) to eliminate adult worms or to reduce access of dogs to larval stages in offal. Major hydatid control campaigns have been introduced in a number of countries including Australia, Iceland, New Zealand, Cyprus, Argentina, and Uruguay. The major measures applied are:

- preventing dogs from gaining access to raw offal at abattoirs and farms or to dead animals in the field
- reducing parasite loads by culling dog populations in combination with mass treatment.

The application of such measures resulted in a rapid reduction of cystic infections in livestock in Cyprus, where over 30 000 dogs were eliminated over a 2-year period. A parallel health education program was also introduced to inform the public about appropriate practices for feeding dogs and for slaughtering animals. A particular problem in hydatid control is that dog feces are used for specific purposes in some areas of the world; for instance, the Turkana of northern Kenya use dog feces to lubricate necklaces, and such feces are used for leather curing in Lebanon. Further problems arise from the inappropriate disposal of animal or even human corpses, and from close relationships between humans and dogs (e.g. 'nurse dogs' in Kenya, or family pets in England). In such cultures, the elimination of dogs cannot be envisaged.

Alveolar hydatid disease (caused by *E. multilocularis*) is a problem in mountainous areas of Europe, northern USA, Siberia, and China, where the fox is the main definitive host and larval (cystic) stages are found in microtine rodents (usually the genus *Microtus*). Health-education campaigns in Europe have successfully discouraged the consumption of wild fruits, particularly blueberries, which can be contaminated with fox feces. In China, reduction of the canine population has resulted in reduced transmission to humans; however, changes in land use associated with loss of forest has increased incidence of alveolar hydatid disease in other areas.

TAENIASIS, CYSTICERCOSIS, AND NEUROCYSTICERCOSIS

Cysticercosis of the central nervous system (neurocysticercosis) is caused by the larval stage (cysticerci) of the pork tapeworm *Taenia solium*. Human beings act as definitive hosts and swine as intermediate hosts. Pigs become infected when they ingest human feces containing *T. solium* eggs, which develop in the muscle and brain into cysticerci. When people eat the undercooked pork of an infected animal, they develop tapeworm infection. Human beings can, however, become infected by directly ingesting *T. solium* eggs from human feces. These eggs then develop into cysticerci, which migrate mostly into muscle (causing cysticercosis) and into the central nervous system where they can cause seizures and other neurological symptoms of neurocysticeriosis. Human cysticercosis infections are acquired by the feco–oral route in areas with poor hygiene and sanitation.

Neurocysticercosis has serious morbidity and is also a leading cause of epilepsy, which has profound social, physical, and psychological consequences. The diagnosis of neurocysticercosis involves the interpretation of nonspecific clinical manifestations, such as seizures, often with characteristic findings on computer-assisted tomography (CAT) scans or nuclear magnetic resonance (NMR) imaging of the brain, and the use of specific serological tests. Diagnostic criteria based on objective data (clinical, imaging, immunological, and epidemiological) have been proposed for different levels of the healthcare system but are not generally used in areas endemic for the disease. Lack of awareness and differences in quality and availability of medical services mean a lack of reporting. Human carriers of *T. solium* are diagnosed by the detection of proglottids or eggs in feces, or by more sensitive methods such as the detection of *Taenia* antigens in stools or specific antibodies in serum.

Human cysticercosis is a disease associated with poverty in areas where people eat pork and traditional pig husbandry is practiced. It is endemic in the Andean area of South America, Brazil, Central America and Mexico, China, the Indian subcontinent, South-East Asia, and subSaharan Africa. The spread of the disease is facilitated by poor hygiene, inadequate sanitation, and the use of untreated or partially treated wastewater in agriculture.

To control cysticercosis, the following intervention strategies are available (Lightowlers 1999):

- Case management, reporting, and surveillance. People with neurocysticercosis usually present with nonspecific neurological symptoms such as epilepsy,

for which adequate case management should be available in health services. Such management requires a consensus on standardized criteria and guidelines for early differential diagnosis in peripheral healthcare structures (with emphasis on resource-poor areas) as well as guidelines for possible treatment or referral to the next level of the healthcare system. Better surveillance and reporting would lead to a more accurate understanding of the extent of the problem and to the identification of foci of transmission.

- Identification and treatment of individuals who are direct sources of contagion (human carriers of adult tapeworm) and their close contacts, combined with hygiene education and better sanitation, will interrupt or reduce the cycle of direct person-to-person transmission, an approach that has been successfully applied to other contagious diseases.
- Universal or selected treatment with praziquantel (10 mg/kg body weight) has significantly reduced the prevalence of human taeniasis in areas where *T. solium* infection is endemic (Mexico). To limit reinfection of humans by the intermediate hosts, treatment should be accompanied by veterinary sanitary measures, meat inspection, improvement of pig husbandry, and treatment of infected animals. Single-dose therapeutic agents, for example oxfendazole, have recently become available, with no deleterious effects on pigs or on the meat product. Animal vaccines are under development.
- Long-term success is more likely when anthelminthic chemotherapy programs are integrated into a wider intersectoral approach to increase public awareness and hygiene practices. Additional measures to sustain the impact of specific interventions include the provision of clean water and sanitation, and health education. Improvement in living conditions, legislation, modernization of swine husbandry, and improvement of meat inspection, have reduced transmission in many industrialized countries.

The International Task Force for Disease Eradication declared *Taenia solium* a potentially eradicable parasite, for the following reasons (CDC 1993):

- the life cycle requires humans as definitive hosts
- tapeworm infections in humans are the only source of infection for pigs, the natural intermediate host
- the transmission of infection from pigs to human beings can be controlled
- no reservoir for infection exists in wildlife.

The strategic use of anthelminthics against adult worms in people and the larval parasite in swine, combined with health education and regulation of pig slaughter, will interrupt transmission, but this approach has yet to be proven in any well-monitored intervention trials.

Taeniasis and cysticercosis do not lead to sudden, large-scale international epidemics and do not seem to constitute an appropriate subject for international notification although Roman et al. (2000) argue that neurocysticercosis should be made an international reportable disease. As with other potentially eradicable diseases, significant progress has been made over the past decade in developing tools, refining strategies, and defining the public health problems. Sotelo (2003) argues that eradication remains an attainable goal, the achievement of which requires more advocacy, resources, national commitment, and global structures. Health ministries should be encouraged to set up surveillance and reporting systems, and adopt an active approach towards prevention and control of these diseases.

Community participation in parasitic disease control

The drive towards primary healthcare following the Alma-Ata declaration of 1978 provoked a greater degree of involvement of communities in healthcare through:

- the use of community leaders to support various programs
- the identification of personnel to undertake health activities on a voluntary basis
- emphasis on the importance of such activities in community well being.

The topic of community participation has been reviewed by Curtis (1991) who provides a series of examples in vector-borne disease control. MacCormack (1991) provides an insight into the underlying principles of sustainable vector control in a community context and reviews the factors that influence success and failure. She emphasizes that much of the success achieved in small pilot programs has depended on particular characteristics such as:

- leadership
- a responsive, well motivated, well educated community
- incentives from agencies and insecticide manufacturers
- ease of communication.

Following initial success, there is a danger that a 'hot' project will fall into a steady state as enthusiasm and donor support wane while the project life-cycle faces inevitable problems. The scaling-up of pilot projects to national ones within a primary healthcare context presents additional challenges. For instance, the community may be affected by the replacement of local leaders with national bureaucracy. In establishing a functional link between the communities and the health systems, each group must be trained to understand the social role on the one hand and technical skills on the other. Communities' local knowledge about insects should be

exploited to aid in vector control. Appropriate control methods, and the importance of maintaining them, must then be clearly explained to all those involved at the local level.

It must also be established whether unpaid community labor can be sustained over time; although it has been achieved in pilot programs, doubts exist about longer term sustainability (Walt 1988). Much is likely to depend on the community structure and its relationship with those in authority, who are perceived as those most likely to benefit. If, for example, a cost-recovery system operates, the volunteers are less able to collect fees from their social superiors. Professional interaction between technicians and volunteers can also fuel conflicts based on perceptions about status.

The outcome of community participation in any project depends on the numerous complex social interactions existing within the community environment. The interaction between weak and strong groups, and the impact of participation on such group relationships, are of critical importance (Antia 1988). It is valuable to define the boundaries of the community involved because individuals tend to identify with a particular locale; this is despite the inherent social instability of most villages, which results from factors such as migration, schooling, and marriage. For practical reasons, the community is usually defined by a geographical boundary such as an urban neighborhood or an agricultural village while nomadic groups represent a mobile community.

Communities differ in how they function and are stratified; for example, they may be democratic, autocratic or under military control. In a democratic environment, obtaining consensus may be a slow process, but the likelihood of sustainability is high. MacCormack concludes that community participation in vector control will be sustainable only if the assessment of the costs-to-benefits ratio takes account of 'opportunity costs' (the value of activities people would undertake if they had not committed themselves to a particular control activity). Sustainability will be enhanced if the following conditions apply: activities are linked to community priorities; skills training enhances community well being; and preventative work links to curative or care outcomes in the primary healthcare setting, or can produce income (Rajagopalan et al. 1987).

Dedicated control programs often achieve good results, but they are often part of a research project. Therefore, coverage of the population in need is relatively small, but delivery costs are high, as are recurrent costs as a proportion of overall costs. This leaves little financial input for operational expenses. In situations in which the frequency of the intervention is limited (e.g. once a year) the commitment of dedicated resources is difficult to justify.

Community-based treatments are usually better targeted and tend to involve volunteers, TBAs, and primary healthcare workers. Increasingly, other types of groups are also becoming involved; examples include women's groups, faith groups, civil society organizations (CSO), and NGDOs. The NGDO community has become increasingly involved in onchocerciasis control. Over the past decade, as the programs in Africa and the Americas have expanded using the donated drug Mectizan® (ivermectin), the momentum for NDGO involvement came from the organizations committed to blindness control that recognized the value of ivermectin as a tool for reducing morbidity associated with onchocercal eye disease (Drameh et al. 2002). At present, NGDOs provide some 25 percent of the resources required for national onchocerciasis programs, and 12 international NGDOs are active in some 20 countries in Africa through the APOC and the countries from the former OCP. The key element of the approach to control is community-directed treatment with ivermectin (CDTI), which is regarded as the key driver in ensuring sustainability of this program. The progress in the APOC program is documented in *Annals of Tropical Medicine and Parasitology*, volume 96, 2002, Supplement 1.

CDTI CHALLENGES

Amazigo et al. (2002) review the challenges presented by CDTI strategies. This approach is based on the principle of community participation but also ensures empowerment by allowing communities to decide who should be the community directed distributors (CDD) and how to plan ivermectin distribution (e.g. dates, location model of distribution). The replacement of the community-based treatment system with the community-directed approach has been encouraged as the latter is likely to be more sustainable, provides community ownership and empowerment and reduces costs to the health system. CDTI enables communities to organize distribution in line with cultural norms and organizational structures – such as kinship and clan structures in Uganda (Katabarwa et al. 2000), while stimulating basic healthcare infrastructure in remote areas (Hopkins 1998). Amazigo et al. (2002) articulate challenges for CDTI into managerial, technical, and sociopolitical headings. These can be summarized as shown below.

Managerial

- Develop drug collection mechanisms/including issues of delay and wastage.
- Integrate with health services including use of CDTI in other health problems and sharing infrastructure and personnel.
- Strengthen infrastructure at all levels to manage and sustain CDTI.

Technical

- Achieve and maintain 65 percent coverage of the total population within all villages (e.g. achieve

100 percent geographic coverall of meso- and hyperendemic villages).
- Address refusals caused by perceptions of adverse reactions.
- Conduct an accurate census using a standard formula for calculating such a census.
- Establish commitment to self-monitoring especially by communities and use the results to improve projects.
- Undertake operational research that identifies problems and apply results.

Sociopolitical

- Increase recognition of role of CDDs and thereby prevent attrition.
- Determine and provide appropriate incentives and motivation for CDDs.
- Involve women as CDDs and in community decisive making.
- Increase involvement and build capacity of local NGDOs.
- Plan and achieve post APOC financial support.
- Achieve balance between cost-recovery strategies compared with guaranteed affordability at all levels; reduce costs.
- Develop advocacy to gain support from political leaders.

The experience that the CDTI concept has provided to date regarding community involvement in onchocerciasis control in Africa gives valuable insights into the link between communities and health systems, which are applicable and generalizable to other programs and have wider policy implications (e.g. cost recovery). However, CDTI may not be applicable in other settings where a high degree of coverage is needed and where health services themselves are better resourced than in rural Africa or in urban settings or conflict situations. The APOC has experienced the value of and problems presented by CDTI in conflict environments where the necessity of convincing communities to engage in onchocerciasis control is a priority: identifying partners prepared to work in insecure areas, and population movement. The needs of CDTI (i.e. high coverage, need for census, selection of CDDs, drug logistics, and monitoring) are difficult to achieve during conflict and civil unrest. Treatment can be given on specific days organized by governments such as independence days, Head of State's birthday, local festivals (e.g. to celebrate harvest or onset of rain). The use of such occasions may reduce the need for intense monitoring to ensure high coverage and compliance. There are no dedicated staff costs, administrative costs are absorbed by the system, transport costs are minimal, compliance is high, and costs of monitoring and evaluation are low. These arguments have been developed to justify such approaches to lymphatic filariasis control in Papua New Guinea. Treatment with DEC was simplified by creating tablets based on a calculation of the average weight of adults and children; the appropriate amount of drug was formulated into one blue tablet for adults and one red tablet for children. This eliminated the need for scales for weighing, allowed the treatment to be administered by untrained personnel and improved compliance (by using a single tablet). The estimated cost per treatment was US$0.8 per child and US$1.2 per adult (not including costs for transportation, health-promotion materials, monitoring, and coordination). In seeking to develop community treatment of any disease, several issues (e.g. devising reporting forms for illiterate communities, drug collection points) need to be studied through locally organized operational research.

Because of the pressures on health systems, it is necessary to use personnel resources at the level of the community to participate in various phases of control activities. This is particularly relevant in the maintenance phase of programs when the community has seen benefits from intervention phases; this promotes confidence between the program participants, the communities themselves, and in health systems. Parasitic disease control programs are increasingly becoming dependent on the involvement of human resources without specific technical knowledge or with only limited training.

In the Chagas' disease control program, Garcia-Zapata and Marsden (1986) have described the value of community involvement in establishing vigilance over the presence of vector bugs following the attack phase. Bug information posts were linked to schools because it was recognized that children were sensitive to the renewed presence of triatomine bugs. Reappearance of bugs is the basis for initiating selective spraying at the local level. If given adequate information, local isolated farmers could also act as notifiers of bug presence. Simple devices for bug monitoring have been developed in Argentina. Similarly, successes in programs to control onchocerciasis, lymphatic filariasis, and Guinea worm have been due to the commitment of communities.

CONTROL OF BRUGIAN FILARIASIS

A focus of filariasis caused by *Brugia malayi* existed in the Indian coastal state of Kerala, in the Cherthala region of Alleppey. There was a high prevalence of the disease with serious clinical manifestations of elephantiasis. The vectors in the area were *Mansonia* mosquitoes that breed on certain water plants (*Pistia*, *Eichhornia*, and *Salvinia*), to which their larvae attach for respiration. The local people believed that vegetation in ponds improved the quality of the water, which was used for domestic purposes. Also, the water plants are used as green manure on coconut plantations (Rajagopalan et al.

1987) and, therefore, the community were reluctant to use chemical larvicides or herbicides.

An extensive education and awareness program was initiated via the media, targeting various sectors of the community. A group of sociologists was used to pass on the necessary technology and to create interest. The Filariasis Patients' Association, headed by a former school teacher, developed a school health-education program. This campaign was targeted towards the female population of Cherthala, who were often not chosen as brides because of filariasis; the effectiveness of the campaign was enhanced by a high level of literacy among the local women. The main control measure was the removal of water plants. The community first had to be persuaded that alternative green manure fertilizers were adequate and that ponds could be cleared without financial loss. As no government organization was available to supervise the weed removal, this was done by the people themselves. To provide motivation, the community was encouraged to culture fish that could be sustained only in weed-free ponds. Species of fast-growing edible fish were purchased from the State Fisheries Department and distributed free to those who agreed to remove weed from their ponds. The economic benefits derived from the fish motivated the community to keep the ponds free of weed, thereby removing the vector habitat.

The program is organized by the peoples' Filariasis Control Movement (FILCO), which supports the following variety of approaches to ensure that the whole community is involved:

- in six secondary schools, Student Filariasis Control Clubs run programs to detect and treat filariasis
- all educational institutions contribute voluntary labor to improve the environment
- the National Cadet Corps and National Service Scheme provide services for filariasis control
- the interns of medical colleges are involved in clinical and diagnostic night camps
- the Departments of Fisheries and Agriculture popularize fish culture and alternative fertilizers.

To publicize the message, hoardings depicting filariasis patients were erected in areas where they would have most impact (markets, hospitals, bus stations, railway stations). The slogan employed was 'Remove weeds and protect yourselves and your future generations from filariasis.' These messages were reinforced by the distribution of films depicting the suffering of a filariasis patients.

In parallel with environmental measures to reduce vector levels, screening and treatment of cases, previously under government control, are now undertaken by voluntary organizations. For instance, 75 filariasis detection and treatment centers are now screening the endemic area and positive individuals are being treated with DEC.

Brugian filariasis appears to have been eliminated from Sri Lanka over the last two decades as a result ofselective chemotherapy using DEC and vector control of *Mansonia* host plants using herbicides. Extensive epidemiological investigations have indicated that *Brugia malayi* is no longer present in previously endemic areas.

GUINEA WORM ERADICATION

Guinea worm infection (dracunculiasis) is the subject of a global eradication campaign, initiated in 1980. The International Commission for the Certification of the Eradication of Dracunculiasis was established by the WHO in the mid 1990s to certify the absence of transmission in member states who applied for such status. Prior to such certification, a process of field visits by members of the Commission must be undertaken to validate the information submitted by the country. A pre-certification period of three years is necessary to be sure that transmission has ceased in previously endemic areas. A reward system is also introduced to ensure suspect cases are thoroughly investigated, and posters plus health education messages via media are used to promote the campaign. To date, elimination of transmission has been achieved in India and Pakistan, and both countries have been certified free of transmission. Much of the success in India can be attributed to the development of safe water supplies during the International Water Decade with the drive to ensure that every village had access to safe water. However, the disease remains endemic in 13 African countries while four countries in Africa (Cameroon, Chad, Kenya, and Senegal) and Yemen are in pre-certification status. While there has been a significant reduction in incidence in many countries, Sudan remains the country with the biggest problem due to civil unrest and population movement over the last two decades; Sudan accounts for around 75 percent of all global cases (Hopkins and Withers 2002). The impact of Guinea worm disease is concentrated at harvest and planting times when infected individuals are incapacitated and unable to farm or to attend school for up to 3 months at a time. The infection is painful, and secondary infections often result when the worms emerge through the skin of the extremities. As there are no effective drugs or vaccines, Guinea worm must be eradicated through a series of measures that require community involvement – filtering drinking water; treating bodies of water with the insecticide temephos to kill copepods, providing safe water, and case isolation (containment) to prevent contamination of water sources. The proportion of cases contained is an important measure of the success of the surveillance system, of the involvement of communities, and as a predictor of the likelihood of cases being detected the following season. In the pre-certification stage, it may be necessary to introduce rumor registers and provide

rewards when detected cases are confirmed. Progress in the eradication program is shown in Figure 5.

The eradication strategy is based on the establishment of a national program in each affected country to survey every affected village, to estimate numbers of cases, and to initiate plans. It is then necessary to establish village-based surveillance, using VHWs to report cases on a monthly basis. Health education encourages the use of cloth filters and the prevention of contamination of water sources. Some villages can also be targeted for provision of safe water while the establishment of a community-based surveillance system (with monthly supervision) might be broadened to cover other major endemic conditions. *Dracunculus*-free certification can be issued to clear areas. To date, there has been considerable success with this approach and incidence has decreased dramatically. VHWs are directly involved in measures that benefit health and increase agricultural productivity and school attendance. Such success increases confidence within communities and motivates them to become involved in other self-sustaining health interventions. A new intervention using portable plastic drinking straws with a filter inserted has been introduced in Sudan to prevent ingestions of copepods.

Community surveillance methods for eradication require the establishment of village development committees whose members are responsible for case notification, health education, distribution and maintenance of filters, and patient care. In Mauritania, this role has been assigned to females who undertake the roles of water gathering and distribution. A potential weakness is that village eradication activities are dependent on monthly supervision from the health personnel at a sub-district level. Each village requires monthly visits, usually integrated with the extended vaccination program or other health programs. Dracunculiasis can be eradicated but needs considerable community commitment from VHWs; in Burkina Faso and Mali, these workers are rewarded by distribution of cloth in recognition of their contribution to the program.

COMMUNITY MALARIA CONTROL IN PONDICHERRY, INDIA

In the coastal areas of Pondicherry, South India, malaria has been controlled by a combination of approaches organized by the Vector Control Research Centre (VCRC). These approaches have achieved good control of the vector *A. subpictus* and also produced income for the local population. Vector control was achieved by removing the algae *Enteromorpha* from coastal lagoons where they sheltered mosquito larvae from fish and other predators. The algae were collected in the pre-monsoon season and provided the raw material for producing paper to be sold by villagers. The lagoon became a focus of mosquito-breeding during the dry season and the villagers were persuaded to deepen one of the ponds in order to allow the other to drain into it, the mud from the deepened pond being used to fill low-lying areas. The deeper pond was then used for prawn culture, which provided extra income for the village.

Control of vectors was also necessary in other breeding sites, particularly the earthenware pots in which coconut husks are retted to make coir. Control was achieved by introducing larvae of the mosquito *Toxorhynchites* which predate larvae of vector mosquitoes. The water filled pits where *Casuarina* trees are grown also act as breeding sites and so these were stocked with the larvivorous fish *Gambusia*. This action was encouraged by using science clubs in schools to stock the pits.

Involving the community initially faced resistance from villagers who were divided among themselves and inherently suspicious of officialdom. These communities placed a higher priority on services such as water, electricity, and roads rather than vector control, except in situations in which malaria epidemics occurred. Only after the VCRC had intervened and asked government departments to provide electricity and a water supply did the villagers have enough confidence to allow vector control projects to commence. The success of this program, as that of filariasis control, was largely due to the initiative of active locally based indigenous scientists (VCRC 1992).

CONTROL OF PARASITIC INFECTIONS THROUGH SCHOOL-AGE CHILDREN

Population increases and investments in education have increased the global population of school-age children. This group is a particularly important entry point for improving health status by using education to create norms of healthy behavior and lifestyle. The school also provides access to a population with a high prevalence of helminth infection in whom mass drug distribution can rapidly reduce morbidity, enhance nutritional status, and improve cognition and hence school performance. Urbanization has increased enrolment into schools, but also promotes conditions such as lack of adequate waste disposal, overcrowding, and the absence of clean water, which may encourage increased transmission of helminth diseases.

A WHO pamphlet (WHO 1995a) estimated that of a global total of 1.2 billion school-age children, 700 million were registered in school with 400 million attending each day, and enrolment still increasing. The target parasitic diseases susceptible to control are schistosomiasis, *Ascaris lumbricoides* infection, *Trichuris trichiura* infection, hookworm infection (*Necator americanus* and *Ancylostoma duodenale*), and infection by the food-borne trematodes (*Clonorchis*, *Opisthorchis*, and *Paragonimus*). Many school-age children have mixed infections, providing justification for mass interventions based on effective single doses of drugs such as the benzimidazoles (mebendazole and albendazole) and praziquantel; these eliminate intestinal helminths and schistosomes.

The epidemiological characteristics of each particular situation require investigation; prevalence and intensity vary even in adjacent areas, as do the pattern and rate of reinfection. It is assumed that reinfection will occur and require retreatment, although emphasizing the importance of personal hygiene should reduce the rate of reinfection. There is thus a need for field studies to ascertain whether intervention for both schistosomiasis and intestinal helminths is warranted. Rapid assessment of hematuria is used to evaluate levels of morbidity due to *S. haematobium* while other approaches are being tested for *S. mansoni* and intestinal helminths.

Drugs for the treatment of intestinal helminths and schistosomes, and their treatment schedules and efficacy, are described by WHO (1995b). Albendazole and praziquantel have now been used in combination; combined drug delivery offers advantages in terms of lower cost and simplification of therapy. This results in improved compliance and improved drug efficacy by potentiation of the therapeutic effect. Trials have provided no evidence of adverse effects of combined treatment with praziquantel and albendazole. Phase I clinical trials showed a four-fold increase in the bioavailability of albendazole in the presence of praziquantel, while the bioavailability of praziquantel was unaffected by the administration of albendazole. Studies on the safety and efficacy of combined treatment have shown no increase in adverse effects and no reduction in efficacy.

The WHO emphasizes the importance of targeting chemotherapy for intestinal helminths at school-age children, as they harbor the most intense infections of *Ascaris*, *Trichiuris*, and *Schistosoma* although intensities of the different worm infections vary considerably between individuals. Treatment of this group achieves the maximum return in terms of reducing morbidity, and schools provide the most accessible entry point for maximum coverage. The WHO also stresses the value of targeting schoolchildren for oral antischistosomal drugs; programs should seek to provide complete coverage of the school-age population. Such approaches could be combined with other helminth control and also with other health-oriented activities such as immunization, nutritional programs, maternal and child health activities, and general health education as part of the school curriculum. Retreatment should not be undertaken for schistosomiasis more than once a year. Epidemiological studies need to be established to evaluate the criteria for retreatment frequency in each area.

The integration of helminth control into the education sector not only fulfils the immediate objective of infection control, but also brings broader health issues to the attention of a group who can strongly influence the behavior of future generations. WHO policy promotes school health programs, with de-worming as an entry point and with an emphasis on personal hygiene. The integration of school-based and community-based chemotherapy into the primary healthcare system will improve coverage and promote optimal retreatment schedules. Another potential benefit may be gained through training personnel at the periphery, who will develop activities based on disease-specific interventions to reduce prevalence and intensity of infection; this will reduce morbidity through coverage of schools and other entry points. While this approach to infection control will undoubtedly improve the health of schoolchildren and, to some extent, contribute to lower transmission rates over time, greater impact will be achieved if health education, improved water supplies, sanitation, and environmental management are integrated into the activities involved in community development.

Role of vector control in disease control

INSECT CONTROL

The role of insects in the transmission of parasitic infections has been recognized since Manson discovered that filaria parasites were transmitted by mosquitoes. From the latter half of the last century onwards, recognition followed that numerous other infectious diseases – sleeping sickness, malaria, Chagas disease, and onchocerciasis as well as various viral infections – were also insect-borne or tick-borne. Knowledge of biology of the vector (particularly of breeding sites, habitat of pre-adult stages, adult resting sites, biting behavior and host preferences, migration capacity and longevity) is a key factor in assessing whether or not appropriate control can be directed at the vector. Early attempts to target malaria by controlling mosquitoes depended on knowledge of larval stages and breeding sites. The removal of breeding sites (source reduction) was the only approach available to reduce vector populations; it was achieved by applying oil and copper compounds and by the rigorous removal or destruction of larval habitats by mechanical methods (WHO 1995c). Tsetse flies were controlled by trapping or destroying savanna and riverine habitats of *Glossina morsitans* and *G. palpalis* group flies, respectively. In some countries, game animals (the favored hosts of *Glossina*) were eliminated by shooting prior to the introduction of cattle. Removal of game animals rapidly reduced the tsetse population in large areas of South Africa, Uganda, and Zimbabwe, providing additional land for ranching.

The advent of chemical insecticides in the 1940s provided new tools for vector control that became incorporated into programs designed to control, if not eradicate, numerous diseases. DDT, initially the most widely used of these insecticides, was (together with chloroquine) a major tool in the campaign for malaria eradication launched by the WHO in 1955. In parallel, DDT was also being utilized in:

- tsetse-control programs for both human and animal trypanosomiasis
- control of *Simulium* (blackfly) larvae to control river blindness
- the successful elimination of *S. damnosum* in Uganda.

Meanwhile, another chlorinated hydrocarbon, benzene hexachloride (BHC), also known as lindane, was successfully used against triatomine bugs in Chagas disease control.

Recognition of the environmental side-effects of chlorinated hydrocarbons, through direct toxicity on nontarget insects and bio-accumulation, led to a suspension of their widespread use and a drive to utilize other chemical classes of insecticide. This was accelerated by the realization that resistance of mosquitoes to DDT was posing problems for malaria control, particularly in indoor house-spraying programs. Attempts were made by the environmental lobby to include DDT in the international treaty to ban persistent organic pollutants (POP); however, the public health utility of DDT has been recognized through the efforts of the WHO which, in the light of impending resistance to synthetic pyrethroids, advocated for its continued acceptability for indoor house-spraying against *Anopheles* vectors of malaria. Hence, DDT can still used in some public health control programs for indoor house-spraying; however, caution is needed and its use should be monitored and the potential for side-effects studied (Curtis 1994). While pyrethroids such as lambacyhalothrin are widely advocated for indoor house-spraying, the major emphasis in malaria vector control now is the drive to increase use, coverage and retreatment of permethrin-treated bednets as part of the Roll Back Malaria strategy. Ambitious targets have been set for the coverage of vulnerable groups (pregnant women, children under 5) but significant issues remain to be resolved in respect of payment for these insecticide-treated nets, subsidy for vulnerable groups, methods for ensuring re-treatment regularly takes place, the role of permanently impregnated nets, and how sustained coverage through the commercial sector is to be achieved given the policy that nets should be available free.

There are, however, many examples where vector control has had a profound public health impact. Outside the domain of parasitic disease, the elimination of yellow fever by source reduction of *Aedes aegypti* in Central America illustrates what can be achieved through intensive and well-organized campaigns of vector control. The elimination of *A. gambiae* from Brazil, following its establishment from West Africa in the 1930s, represented not only an important public health achievement but also a major contribution to the development of Brazil, given the efficiency of *A. gambiae* as a vector of malaria in Africa.

Currently, intensive programs are underway to eliminate *Triatoma infestans* (the vector of *Trypanosoma cruzi*) by domiciliary spraying using the synthetic pyrethroids (deltamethrin and lambacyhalothrin) in the Southern Cone countries of South America. This has had a major impact on transmission, as determined by standardized serological procedures and community-based bug-monitoring systems in Brazil, Argentina, Paraguay, Chile, and Uruguay. Figure 4(a–d) demonstrates the success of the program in terms of impact on transmission by incidence and by levels of house infestation. Applied research has been geared towards providing additional methodologies to support government-organized control schemes such as fumigant canisters, insecticidal paints, and simple bug-monitoring devices for surveillance of reinvasion. The Chagas disease control programs do not benefit from having an effective chemotherapeutic agent. This has extended the anticipated time for reducing Chagas disease as a public health problem because no drug or vaccine is likely to become available in the foreseeable future. Hence, the current approach of intensive vector control supported by national governments is the only feasible one (WHO 1991) with screening for infective bloodmeals.

To achieve the objectives of the OCP, vector control has been the core strategy in 11 countries in West Africa. The program, initiated in 1974, was based on larviciding the breeding sites of *S. damnosum* complex blackflies, initially in six West African countries. The strategy was based on the need to break the life cycle for the lifetime of the adult *Onchocerca volvulus* which, in 1974, was considered to be 18–20 years. At that time, only one insecticide (the organophosphate, temephos) had the appropriate chemical characteristics to satisfy the environmental prerequisite of avoiding long-term damage to the riverine ecology. Two major problems faced the program early in its existence: migration of savanna blackflies from outside the program area, and resistance of some blackfly populations to temephos. These problems were solved by extending the area of the program westwards and southwards and by engaging in a research program that rapidly developed alternative insecticides. The extensive activities of the OCP and its management and structures are described by Samba (1994), Molyneux (1995), and Boatin et al. (1997). At present, seven larvicides from different chemical classes are in operational use They are used on a rotational basis in accordance with parameters such as cost-effectiveness, environmental side-effects, river discharge rates, carry distance of insecticide, and risk of resistance development. The seven insecticides in current use (Hougard et al. 1993; Yameogo et al. 2004) are:

- *Bacillus thuringiensis israeliensis* H–14 serotype toxin (Bti)
- temephos, phoxim, and pyraclofos (all organophosphates)
- carbosulfan (a carbamate)
- permethrin (a pyrethroid)

- etofenprox also known as vectron (a pseudopyrethroid).

While vector control has been successful in breaking the onchocerciasis transmission cycle, the necessary duration of vector control has been reduced by the widespread use of ivermectin; this became available for use as a microfilaricide suitable for use in communities in 1986 (Remme 1995). Epidemiological studies indicate that the duration of adult worm life is 14 years and that distribution of ivermectin in hyperendemic areas on an annual basis rapidly reduces microfilarial loads and also has a rapid impact on ocular morbidity. Hence, combined vector control and chemotherapy reduce the duration of control to a 12-year period although ivermectin alone, at least in the African endemic areas, appears not to prevent transmission (Winnen et al. 2002).

Increasing numbers of displaced persons and refugees pose special problems for organizations responsible for management of disease. Intervention through vector control is an important component, as there is great potential for rapid disease outbreaks in crowded, unsanitary environments that support traumatized, malnourished, displaced individuals who are exposed to vector-borne infection or ectoparasites. Epidemics are sometimes most effectively controlled through vector control. Thomson (1995) provides details of how such epidemics should be controlled, with specific reference to relief organizations. The conflict-associated parasitic disease problems are shown in Table 2.

SNAIL CONTROL

The elimination of snails for the control of schistosomiasis remains an important component of control activities and three approaches have been used: chemical, environmental, and biological. Projects in several countries have shown that chemical control using molluscicides (e.g. niclosamide) in combination with other methods can reduce or eliminate transmission. Chemical molluscicides must be environmentally acceptable and must not produce adverse side-effects if they enter the food chain. In addition, they must be cost-effective, snail-specific, and easily applied. During the 1970s, snail control, either by chemical methods or through environmental management (weeding, irrigation-canal construction, and maintenance), was a key control component. The advent of safe and effective chemotherapy for schistosomiasis (oxamniquine, praziquantel) capable of reducing morbidity through population-based campaigns has shifted emphasis away from molluscicide. Snail control is now considered as one of several approaches in integrated morbidity control, contributing to reduction in transmission at times of peak transmission. Target levels of reduction of snail populations should exceed 95 percent and must be maintained throughout the main season of transmission. Molluscicides can be used to destroy snails in breeding sites in transmission foci, reducing transmission in recreational areas such as lakes. They are also useful in the following ways (McCullough 1992):

- as a means of reinforcing community involvement
- to reduce transmission in areas where there is a special risk (e.g. fishing villages in the Volta Lake, Ghana)
- to eliminate newly introduced snail populations
- for total elimination of snails in isolated focal transmission sites (e.g. oases in North Africa)
- to prevent the establishment of dense populations in irrigation schemes.

Biological control of the snail hosts of schistosomes has been attempted by introducing other snail genera or species to out-compete the natural hosts but the impact of this approach on schistosomiasis morbidity has been limited.

Population-based chemotherapy, combined with local and seasonal use of molluscicides, will be the central features of future schistosomiasis control in high priority foci. Molluscicide must be planned effectively and better strategies and delivery systems are required to improve cost-effectiveness. New, inexpensive but effective synthetic molluscicides are needed in addition to bayluscide, the only compound currently commercially available (WHO 1993b).

Role of chemotherapy and chemoprophylaxis

Drugs are the mainstay for controlling many diseases, but antiparasitic drugs present a considerable challenge for researchers interested in rational drug development. Investment by multinational drug companies in new agents for use in the tropics and the developing world is limited because the markets themselves determine the research and investment strategies of the pharmaceutical industry.

Parasite infections pose a variety of other problems for chemotherapeutic control:

- the organisms rapidly develop drug resistance
- effective compounds have a narrow therapeutic index and hence side-effects are common
- parasites can invade specific sites of the body making drug delivery difficult
- helminth parasites can be relatively large and require proportionally more drug than microscopic organisms
- compounds may be difficult to obtain when required and manufactured only infrequently, particularly those compounds used for treatment of diseases that affect relatively small numbers of individuals
- some currently used compounds contain toxic elements such as arsenic and antimony

- many compounds must be administered under medical supervision, require hospitalization, and are neither accessible nor affordable by individuals.

Despite these problems, some compounds are highly effective for controlling parasitic infections and for the treatment of individuals. New drugs for human diseases have also originated from alternative sources over the last decade. For instance, veterinary research produced ivermectin, used for treating onchocerciasis, lymphatic filariasis and scabies; ivermectin was originally marketed for the treatment of helminth infections of animals. Eflornithine, a drug that can cure late stage chronic sleeping sickness, was originally developed as an anti-tumor drug. The artemisine derivative qinghaosu, produced from the Chinese herb *Artemisia* and used as a cure for fever in China for 2 000 years, is now widely available for malaria treatment. Its availability is often uncontrolled, which will encourage rapid development of resistance. In addition, as with many well-used drugs, fake products are becoming widely available. This is of concern because the drug has valuable curative properties and, therefore, should only be introduced in appropriate circumstances in relation to the current drug-resistance spectrum of malaria parasites in each region. New formulations of existing drugs have been developed, such as encapsulated liposomes that provide slow release of a drug; a slow-release formulation of amphotericin B (AmBisome) has been developed to reduce toxicity and enhance efficacy in leishmaniasis treatment.

A distinction must be made between drug treatment initiated to alleviate individual suffering, and mass treatment strategies that seek not only to improve the well being of individuals, but also that of communities. This latter objective is achieved by ensuring that no parasites can be transmitted by vectors, or that no parasites remain to reinfect the population. Drugs must, therefore, be regarded as having several functions in control. Gutteridge (1993) provides a summary of the drugs available for parasitic diseases and the rationale for their use. Tables 12, 13 and 14 summarize the drugs available for treatment of the diseases discussed in this chapter.

A major problem in many parasitic diseases is that drug resistance frequently arises. Management of drug resistance in parasitic disease is difficult as there are few alternative compounds available. Strategies for reducing the likelihood of the development of drug resistance in malaria and helminth diseases are well documented and include the following:

- appropriate dosage regimes
- control of drug quality and distribution (in malaria)
- incorporation of vector control to reduce the development or spread of resistance.

Mechanisms responsible for development of resistance (Gutteridge 1993) include:

- the ability of the organism to metabolize the drug to an inactive form
- changes in the permeability of the organism so that the drug is no longer taken up
- development of alternative biochemical pathways
- increased levels of target enzyme production
- a change in the biochemical target so that the drug cannot bind as well as it did to the original compound.

The ability of microorganisms to change and adapt rapidly will clearly represent a continuing problem and drug resistance is unlikely to be avoidable. Hence, any disease control strategy based on chemotherapy should anticipate such a problem and should seek to reduce the rate at which resistance develops, while also promoting strategies for management of resistance if it occurs.

In many developing countries, drugs are available through many sources. From the perspective of the consumer, the availability of drugs at a health facility is a major indicator of quality of care. In the poorest households, up to 50 percent of expenditure on health is on drugs, many of variable quality (counterfeit, expired). In the developing world, pharmaceutical expenditure accounts for 20–30 percent of recurrent costs; it is second only to personnel costs (World Bank 1994). Supply of drugs for the control of parasites is usually organized in the public sector through government-formulated essential drug lists. The WHO essential drug list (WHO 1992b) and program includes drugs for the treatment of infection with parasites. The concept of an essential drug list is that such drugs should be available at all times, in adequate amounts, and in the appropriate dosage forms (WHO 1992b). Several important drugs used for parasite disease control are often unavailable, despite being specified on essential drug lists.

While governments have a responsibility to provide essential drugs to different levels of the health service, private providers play a major role in many countries where private expenditure on drugs considerably exceeds public expenditure. In Africa, c. 70 percent of the population has no regular access to essential drugs and drug stocks often run out as a result of problems with management, logistics or finances. This is particularly true in peri-urban and urban centers, even to the extent that hospitals may run out of drugs. Drug shortages are less frequent in commercial facilities and such supplies are more readily available in urban centers, but the perception of higher quality product availability in the private sector allows for prices to be inflated. Private suppliers are also frequently not subject to quality control. In the case of antimalarials, which are among the most frequently required drugs, there is overpricing and supply is irregular while fake and adulterated products are promoted by importers. Antimalarials are often supplied without diagnostic confirmation.

The problems of drug supply, cost (generic versus brand name), quality control, distribution, irrational prescribing, noncompliance, and availability have been highlighted by the World Bank (1993, 1994). These problems potentially apply to all drugs, and awareness of them and the ways to circumvent them must be addressed if chemotherapy or chemoprophylaxis is to be a more effective part of disease control. Other problems may arise if vertical programs involving donated drug distribution are developed; for example, the distribution of ivermectin for onchocerciasis and albendazole for filariasis. Such an approach may conflict with the development of revolving funds to sustain drug supplies at primary healthcare centers, as might distribution for control of schistosomiasis or intestinal helminths targeted through school health programs. In the increasing number of emergency situations, the agencies involved need to be aware of the potential needs of the affected populations as part of their response planning. In this context, a predictive approach to supplying drugs (and insecticides) is necessary and must be based on a knowledge of the ecology of the area and the likely disease problems.

The use of reliable, systematic reviews of evidence of effectiveness to inform policy is becoming recognized as a vital contribution to enabling resources to be used appropriately. The Cochrane Collaboration has developed a series of systematic reviews of randomized control trials that provide a reliable assessment of the effectiveness of various healthcare interventions. This approach has been promoted because traditional reviews are unsystematic and neither respect scientific principles nor control for bias and random error. The approach involves worldwide partners and is designed to build on enthusiasm for the process, to minimize duplication, to avoid bias, to maintain an electronic database, and to ensure wide access in order to make the information available to decision makers. A list of the Cochrane reviews and protocols can be found at www.cochrane.org/cochrane/revabstr/g070index.htm.

The Parasitic Diseases Group is currently compiling a register of published and unpublished trials in parasitic diseases, identified by hand-searching relevant journals, using editors in China, Chile, the USA, and the UK. The review topics include malaria chemoprophylaxis in pregnancy, the use of artemisine derivatives in malaria, chemotherapy of filariasis, and the treatment of neurocysticercosis and giardiasis.

Role of diagnosis in control

Diagnosis of an infection or disease is a fundamental concept of curative medicine. In some parasitic infections, identification of more than simply the presence of the organism is essential if the appropriate treatment is to be given. For example, in sleeping sickness it is important to confirm the stage of the disease, as well as the presence of the parasite; this is because the drug-based treatment for late stage disease (melarsoprol) can be fatal. Hence, treatment is not initiated without confirmation of central nervous system involvement. In other diseases with high prevalence of infection in which mass treatment campaigns are in operation, diagnosis of the individual is not important. Diagnosis of malaria can only be confirmed by microscopical diagnosis; this is rarely undertaken in many settings in Africa. Clinic-based presumption diagnosis is often not malaria and this fact, together with first-line treatment-seeking behavior outside the formal public health sector, means few patients are correctly diagnosed. This results in over-consumption of antimalarials with unwanted consequences for drug resistance as well as increased cost to poor people.

In some diseases, such as schistosomiasis, onchocerciasis, and lymphatic filariasis, for which the overall prevalence is high, it is important that available resources are concentrated on those populations most in need. Therefore, the concept of rapid appraisal of disease burden in various communities has developed so that interventions can be better targeted. Ngoumou et al. (1994) described such an approach to the rapid mapping of hyperendemic onchocerciasis using nodule frequency, which correlates closely with community microfilarial load, as a means of targeting ivermectin distribution. The frequency of hematuria can be used as an indicator for the prevalence of schistosomiasis in school children. Recently, the rapid assessment of prevalence of eye worm (RAPLOA) technique, which uses the local name for the tropical eye-worm symptoms with a photograph of the worm passing through the eye or the presence of Calabar swelling, has been developed in communities in southern Nigeria and Cameroon. Recognition of the condition is valuable in prediction of endemicity.

There is, therefore, a trend away from 'gold standard' parasitological diagnostic techniques when disease-control programs are underway. This does not diminish the importance of diagnosis of the individual infection in need of specific treatment. The need to maintain diagnostic parasitological skills remains, and is particularly relevant, in the provision of diagnostic staff for microscopic diagnosis of malaria. Identification of parasites and differential diagnosis of *Plasmodium* species are important not only in determining treatment but also in saving unnecessary expenditure on drugs by defining whether or not a fever is of malarial origin. Despite the continuing need for skilled microscopists for malaria diagnosis, the amount of training provided is often inadequate, as are the quality of microscopes and staining materials available.

Serological diagnosis for screening populations has been used for surveillance of sleeping sickness. An antibody detection test, the card agglutination test for trypanosomiasis (CATT), and antigen detection tests are used

to screen populations. In those suspected of infection, parasites are detected by examination of blood or lymph by direct or concentration techniques. Similarly, a direct agglutination test (DAT) has been developed to identify suspected cases of visceral leishmaniasis; this should be followed by a parasitological diagnosis, usually by the examination of bone marrow aspirate or splenic biopsy. These techniques are painful and risky, respectively, and not applicable to large numbers of cases.

Diagnostic developments include tests to detect antigens in urine – dip-stick techniques based on enzyme-linked immunosorbent assay (ELISA) systems and using color change as an indicator of the presence of antigens. In the case of urinary schistosomiasis, a color test is used to indicate the presence of blood.

Lymphatic filariasis due to *Wuchereria bancrofti* (and *Brugia malayi*) poses particular problems for diagnosis as the parasites appear in the blood only at night, when it is often difficult to take blood smears. Methods for detection of parasite antigen (Weil et al. 1997) or DNA represent more effective ways of obtaining information about the endemic status of filariasis and of monitoring the impact of control. Nevertheless, while such testing is being evaluated, parallel confirmatory night-time blood samples also need to be taken for monitoring and evaluation purposes at sentinel sites in control programs. Evaluation of lymphatic filariasis programs would also benefit from the availability of a test to detect antibodies resulting from exposure to infective larvae (L3) as a measure of effectiveness of transmission control. The importance of the continuing of monitoring and evaluation throughout a program allows programs to be determined by different methodologies (Figure 3(a–c) and Figure 4(a, b)). It is important to define the role of different age groups in the population in order to focus on incidence following interventions as a true measure of the impact and efficacy of the intervention while recognizing the sensitivity and specificity of any test as well as the sampling frame involved and the sensitivity of the expected population size to census error in defining real incidence prevalence or coverage if an arbitrary figure of success is selected.

There is also a need to develop an alternative diagnostic test to detect onchocerciasis in areas where the disease has been controlled, as skin snipping is no longer acceptable and both prevalence and microfilarial load are low. Here, it is important to determine if transmission is occurring and, although this is undertaken by examining blackflies, this may not be feasible. The ideal requirement for onchocerciasis serological diagnosis would be a test in humans to detect the pre-patent developing adult worm stage of the infection when few if any microfilaria have reached the skin.

The role of diagnosis in the control of parasites varies depending on how the question is approached; for instance, the following factors may need to be compared:

- treatment at the level of the individual for cure versus treatment at the level of the community for control
- safe drug versus toxic drug as a life-saving option
- expensive intervention versus cost-effective intervention
- cheap drug versus free drug
- monitoring control versus obtaining baseline data on prevalence pre-intervention.

The appropriate diagnostic approach depends on the particular situation.

Control of intestinal parasites

The impact on morbidity of intestinal helminths and, to a lesser extent, protozoal infections due to *Entamoeba* and *Giardia*, has been highlighted by the recognition that their public health impact was previously grossly underestimated (Table 1). There is now a body of evidence suggesting that intestinal helminths (*Ascaris*, *Trichuris*, and hookworms) have significant effects on growth, nutritional status, and school performance in children. The opportunity to provide alleviation of worm burdens through single dose, effective, inexpensive drugs (albendazole, mebendazole) is currently being exploited. This approach provides direct benefits as the worm burden is removed, reducing morbidity, and also possibly reducing the rate of transmission. Repeat treatment ensures that burdens are maintained below levels associated with morbidity, preventing protein–energy malnutrition and iron-deficiency anemia.

It is recommended that treatment for intestinal helminth infections is administered without prior screening as prevalence is high. The school-based approach is one of a range of strategies that can be used for helminth control at the community level; it can be integrated into existing systems such as maternal and child healthcare, family planning, water supply, and sanitation, and should be reinforced through health education. In areas where schistosomiasis is endemic, control approaches can be combined, reducing costs, improving compliance, and facilitating the logistics of control. In the longer term, health education, improved environmental sanitation, and safe water supplies are the components essential for the reduction of morbidity caused by intestinal parasites transmitted by the oro–fecal route or through the skin. In school-based programs, it is vital to train teachers about prevention and control, and these topics should be included in the curriculum.

There are continuing plans in some countries for major parasitic disease control programs. China has commenced a national de-worming program for a population of 200 million children; in Mauritius, the World Food Programme is including de-worming in a school meals initiative.

Table 5 *Stratification of malaria epidemiology in relation to approaches to control (after WHO 1993a)*

Malaria type (geographical distribution)	Epidemiological characteristics	Operational	Action required	
			Disease management	Prevention
Savanna malaria. Sub-saharan Africa, Papua New Guinea.	*Plasmodium falciparum* dominant parasite. Perennial transmission but varying seasonality depending on distance from equator. Mortality and morbidity in young children and pregnant women. Drug resistance increasing problem.	Limited coverage by health services. Malaria control programs inadequate. Deficiency of appropriate capacity. Recognize interactions between HIV/AIDS and malaria treatment, control and policy. Increase access of poor to effective service	Increased interest of government, NGO, and private sector in malaria disease. Strengthen capacity for management of severe and complicated malaria. Improve diagnostic services, particularly in view of increased drug costs. Introduce appropriate national drug policies.	Implement impregnated bednets and curtains. Chemoprophylaxis for pregnant women unless precluded by drug resistance.
Malaria of highland or desert fringe (Africa, South East Asia highland; Sahel, South Africa, and South Pacific).	Risks of epidemics due to climate, conflict, changing agriculture practice or migration patterns. Drug resistance an increasing problem	Health services not available or limited. Terrain and distance present obstacles to control. Poor management of malaria where not historically a problem.	Establish epidemic preparedness, strategies, and policies. Active case detection and treatment of fever may be justified. Health services must be made aware of risk potential.	Vector control might reduce or eliminate transmission, particularly indoor residual spraying
Malaria of plains and valleys outside Africa (Central America, China, Indian sub-continent)	Variable, mainly moderate transmission. *P. vivax* may dominate. Strong seasonal variation. Drug resistance established.	Vector control not effective. Inadequate disease management. Health services inadequate; private services available.	Ensure responsibility of malaria control with general health services. Strengthen epidemiological systems.	Improve vector control if cost-effective. Environmental management might have impact hence intersectoral links necessary. Bednets can be useful (China).
Agricultural development projects. All malarious areas.	Increased transmission sometimes associated with irrigation. Seasonal malaria outbreaks in non-immune immigrant workers. Predictability of impact of change difficult to assess.	Insecticide resistance in cotton-growing areas. Finance for malaria control more likely to be available.	Establish services for treatment or strengthen existing ones.	Environmental management should be considered. Site and construct habitation appropriately. Impregnated bednets for labour force. Larvivorous fish in rice growing areas. House spraying and chemoprophylaxis appropriate for work force. Personal protection.

(*Continued over*)

Table 5 *Stratification of malaria epidemiology in relation to approaches to control (after WHO 1993a) (Continued)*

Malaria type (geographical distribution)	Epidemiological characteristics	Operational	Action required	
			Disease management	Prevention
Urban and peri-urban malaria (Africa, South America, South Asia).	Transmission and immunity variable. Increasing drug resistance.	Relatively good access to health services. Antimalarials available from different sources. High human population density. Breeding sites identifiable.	Standardize and harmonize treatment practices. Introduce drug quality and control systems. Facilities specific for malaria treatment required.	Personal protection and prevention. Impregnated bednets.
Malaria of forest and forest fringes South East Asia, South America.	Focally intense transmission. Occupational risk groups (e.g. mining). Severe multi-drug resistance. Non-immune migrant labour at high risk.	Health services inadequate or absent. No or limited social organization in communities. Variety of drugs sold via different outlets. Vector-control efficacy doubtful.	Treatment needs to be continually adjusted depending on experience of response to drug regimes. Establish communication between medical staff involved in treatment. Information, education, and communication of the private sector providers.	
War zone malaria. Conflict/ refugee emergency malaria.	Displacement of parasite-carrying population or non-immunes. Environmental degradation increases mosquito breeding.	Disruption of vector control. Limited curative services available. Drug distribution only via humanitarian assistance. Drugs provided may be inappropriate.	Awareness by responsible authorities of malaria risk. Drugs for treatment available via emergency programs must be appropriate to drug resistance pattern prevailing. Establish treatment facilities.	Refugees and soldiers may be protected by personal protection/chemoprophylaxis for vulnerable groups. Environmental measures and chemical control in refugee camps.

Table 6 *Stratification of epidemiology of African and South American trypanosomiasis in relation to control*

Disease and geographical locality	Epidemiological characteristics	Operational approach	Disease management	Required prevention
Rhodesiense sleeping sickness. East and Central Africa. *T. b. rhodesiense* Vector: *Glossina morsitans*, *S. pallidipes*. *G. fuscipes* in Uganda and Kenya epidemics	Usually zoonosis with range of game and domestic animal reservoirs. Transmission associated with entry into areas where savanna flies feed on game animals. Vector control inappropriate, occupation-associated transmission (e.g. honey gatherers, fishermen, poachers). Epidemics associated with human-to-human transmission by *G. fuscipes* with domestic cattle as reservoir hosts.	Acute disease. Passive case detection in local health facilities by routine diagnostic techniques. Need for active case detection and treatment centers in epidemics.	Accurate disease stage diagnosis; availability of drugs; recognition of toxicity of arsenicals and provision of treatment and care for serious adverse events	Avoidance of high risk areas. No vectors or reservoir control directly targeted but animal trypanosome control by vector control may have impact. Treatment of domestic livestock with trypanocides may reduce human cases. Epidemics stemmed by active case detection and vector control to reduce transmission (traps and targets)
Gambiense sleeping sickness. West and Central Africa. *T. b. gambiense*. Vector: riverine flies, *G. palpalis* group	Person-to-person transmission via riverine flies. Animal reservoirs of limited importance. Site associated transmission around high humidity areas.	Active case detection followed by treatment. Diagnosis by low parasitemias insensitive hence serological tests of value for screening. Vector control to arrest epidemic and halt transmission.	Provide diagnostic facilities at primary health care (PHC) and district level. Ensure drug availability. Maintain surveillance to detect early cases facilitating easier treatment. Provide adequate medical support for treatment and resuscitation in view of risk of side-effects to melarsoprol.	Vector control by community (traps); residual spraying of resting sites. Maintain surveillance to reduce epidemic risk. Prophylaxis with pentamidine no longer employed.
Chagas Disease. South and Central America. *T. cruzi*. Vector: triatomine bugs *Triatoma infestans* in Southern Cone	Zoonosis transmitted by intradomiciliary bugs. High vector infection rate. Many reservoir hosts. Acute disease in children but chronic in adults.	Diagnosis of chronic disease difficult and no effective remedy if diagnosed. Acute disease treatable but drugs expensive and toxic.	Limited efficacy of chemotherapy provides poor prognosis with death through cardiomyopathy. Transfusion disease averted by control of blood via trypanocidal additive (gentian violet).	Vector control by indoor house spraying or other insecticidal approaches – paints, fumigant cans. Improved housing provides beneficial long-term effect.

Table 7 *Stratification of epidemiology and control of leishmaniasis*

Disease and geographical locality	Epidemiological characteristics	Operational approach	Disease management	Prevention
Old World visceral leishmaniasis. Indian subcontinent. *L. donovani*. Vector: *P. argentipes*.	Anthroponotic subclinical cases frequent. No animal reservoir. Endemic with periodic epidemics.	Capacity to diagnose is limited. Antileishmanial drugs expensive, toxic, and not easily available. Inadequate reporting and case follow-up. Parasitological diagnosis to be available at district level with serological examination at PHC level if serodiagnostic capacity exists.	Improve diagnostics. Active case detection to reduce human reservoir.	Possible use of impregnated materials or residual insecticide application in epidemics to reduce transmission by sandflies.
East Africa. *L. donovani*. Vectors: *P. orientalis*; *P. martini*.	Reservoir hosts (rodents, carnivores) likely but importance unknown. Suggested association with termite hills in Kenya. Epidemic in S. Sudan associated with movement of population and development of *Acacial Balanites* woodland.	Passive case detection and treatment. Annual incidence requires to be checked by active surveillance. S. Sudan epidemic places major demands on availability of Pentostam worldwide.	Improved diagnostics and drug availability.	Reservoir or vector control not feasible.
Visceral leishmaniasis with canine reservoir or assumed canine reservoir. North Africa, Middle East, Central and South America. *L. infantum*. Vectors: *Larroussius* subgenus; *P. perfiliewi*, *P. perniciosus*, *P. ariasi*. New World *Lutzomyia longipalpis*.	Zoonotic disease with foxes and dogs as reservoir hosts. Endemic over wide area; epidemics are infrequent. Sporadic cases over wide area with subclinical cases likely to be common. Found more frequently in children .	HIV-associated increase in cases in southern Europe through intravenous drug users. Vector control using insecticide impregnated collars on dogs. Diagnosis and treatment of dogs in endemic areas of Mediterranean and S. America has little impact. Reservoir control useful but has limited impact where feral reservoir hosts exist.	Ensure a minimum capacity for passive case detection and treatment.	Serological monitoring and treatment of dogs in Mediterranean. Use of insecticide impregnated collars on dogs.

(*Continued over*)

Table 7 *Stratification of epidemiology and control of leishmaniasis (Continued)*

Disease and geographical locality	Epidemiological characteristics	Operational approach	Disease management	Prevention
Anthroponotic cutaneous leishmaniasis. Old World urban centers. *L. tropica*. Vector: *P. sergenti*.	Predominantly found in densely populated settlements. Person-to-person transmission by *P. sergenti*. Incidental hosts not important. Transmission seasonal after sandfly peak.	Passive case detection as a minimum to reduce human reservoir. Integrate any vector control activities (house spraying, impregnated nets, and targets) with malaria control (but rarely sympatric).	Ensure awareness of disease; transmission, diagnosis, and treatment. Ensure drug availability.	Human reservoir control by active case detection. Vector control by residual insecticides in houses where cases found. Check susceptibility of vector to insecticide. Malaria control by house-spraying has impact as do bednets; use of impregnated materials feasible.
Zoonotic cutaneous leishmaniasis. Arid rural areas of Old World. *L. major*. Vectors: *P. papatasi*, *P. dubosqi*.	Reservoir (rodent)/sandfly transmission systems: *Rhombomys*/*P. papatasi* (Asia). *Psammomys*/*P. papatasi* (Middle East/N. Africa). *Arvicanthis*/*P. dubosqi* (sub-Saharan Africa). Settlements around rodent colonies at risk; also workers (e.g. construction) who enter arid environment with rodent colonies.	Passive case detection and treatment with drugs. Live vaccines used in military situations. Rodent control/environmental control possibly effective. Self-healing lesions with total immunity, but high level of disfigurement.	Awareness at health facilities. Availability of drugs.	Leishmanization has been used but 2.5 percent have large nonhealing lesions. Vector control not a cost-effective option. Environmental measures to prevent rodent establishment (e.g. plowing, poisons, flooding).
Zoonotic cutaneous leishmaniasis. East African highlands. *L. aethiopica*. Vectors: *P. longipes*, *P. pedifer*.	Association with hyraxes. Human cases associated with the proximity to hyrax colonies.	Case detection. Epidemiological knowledge of high-risk areas by health services.	Awareness at PHC level of clinical presentation; availability of antileishmanials.	Hyrax eradication possible locally. Vector control ineffective.
'Uta' cutaneous leishmaniasis. Andean highlands/western Cordilleras. *L. peruviana*. Vector: *Lu. peruensis*.	Putative reservoir hosts are rodents (*Akodon* and *Phyllotis*) and dogs. Seasonal transmission. Lesions predominantly in children below school age.	Passive surveillance. Case monitoring.	PHC awareness and case reporting.	Value of vector control is unknown except where proven peridomestic transmission.
Cutaneous leishmaniasis in Northern South America. *L. guyanensis* Vector: *Lu. umbratilis* (possibly *Lu. whitmani* and *Lu. anduzei*).	Forest edentates (Sloths *Choleopus* and anteater *Tamandua*). Reservoir hosts have high infection rate. *Didelphis* (oppossum) secondary peridomestic reservoir hosts where ecology has altered.	Humans infected by encroaching into forest or by establishment of habitation at forest edge.	Case detection and treatment. Availability of antileishmanials.	Vector control of limited impact. Clearing forest up to 300m from habitation reduces incidence.

(*Continued over*)

Table 7 *Stratification of epidemiology and control of leishmaniasis (Continued)*

Disease and geographical locality	Epidemiological characteristics	Operational approach	Disease management	Prevention
Cutaneous leishmaniasis in Central America/Northern South America. *L. panamensis*. Vectors: *Lu. trapidoi*, *Lu. gomezi*, *Lu. ylephiletor*, *Lu. panamensis*.	Also associated with forest penetration or association with secondary forest. Variety of reservoir hosts: edentates, primates, dogs, and rodents.	Passive case detection; awareness of risk for those entering or living in forest.	Case detection and treatment. Availability of antileishmanials.	Clearing of forest around villages reduces transmission. Vector and/or reservoir control not practicable.
Cutaneous and mucocutaneous leishmaniasis in Central and South America. *L. braziliensis*. Vectors: *Lu. wellcomei*, *Lu. intermedia*, *Lu. whitmani*.	Infection associated with forest activities and clearing land. Perennial transmission with high incidence in at-risk groups. Reservoir host not proven and many suspected vectors. In urban/peri-urban environment dogs, horses and pigs have been incriminated as reservoir hosts.	Espundia (mucocutaneous lesions) develop after varying periods following self-healing primary lesions.	Passive case detection; availability of drugs. Essential care of espundia cases to reduce sequelae of lesions. Commercially available vaccine probably not efficacious.	No vector or reservoir control applicable in forest but vector control possible in peri-urban situations, personal protection might help if affordable.
Cutaneous leishmaniasis in South and Central America. *L. mexicana* complex. Vectors: *Lu. olmeca*, *Lu. flaviscutellata*.	Variety of ecological situations – wet forest in Igapo, Brazil; dry forest in Yucatan; fringe forest in Dominican Republic. Rodent and marsupial reservoir hosts; highly dispersed and diverse.	Associated with penetration into forest environments.	Passive case detection, PHC, awareness, and availability of drugs.	Reservoir and vector control not possible. Personal protection in forest; reduce risk by not sleeping in forest. Health education.

Table 8 *Stratification of epidemiology and control of onchocerciasis*

Geographical locality	Epidemiological characteristics	Operational approach	Disease management	Prevention
Africa				
South of Sahara. Former OCP countries.				
1 Original areas: Benin, Burkina Faso, Cote d'Ivoire, Ghana, Mali, Niger, Togo.	1 Savannah woodland of northern tropics. Hyper-endemic villages close to rivers. Historically associated with high blindness rate resulting in depopulation. Major migratory vectors in savanna are *S. damnosum* and *S. sirbanum*. Annual transmission potential of more than 100 was associated with high blindness risk. Disease controlled by vector control since 1974 except in limited areas of Togo (Oti basin)	1 Vector control by weekly aerial larviciding for 14 years eliminates adult worms in human reservoir. Ivermectin twice per year for foci with inadequate vector control.	1 Vector control applied due to lack of availability of community-based drug until 1986. Thereafter, ivermectin for morbidity control to reduce community microfilarial load (CMFL) and arrest development of ocular lesions.	1–6 Maintain surveillance system for recrudescence using tests for early detection of transmission. Institute ivermectin if appropriate. Establish appropriate surveillance via integration into public health systems. Possible detection of early transmission by detection of infective larvae in blackflies. Maintenance of ivermectin distribution. Ensure high and sustainable delivery via community-directed treatment assisted by NGOs.
2 Extension areas: southern areas of Ghana, Togo, Benin; western extension to Guinea, Guinea Bissau, Sierra Leone, Senegal.	2 In forest areas, less blinding form of *O. volvulus* transmitted by forest vectors *S. soubrense*, *S. yahense*, *S. sanctipauli*, *S. squamosam*, *S. leonense* (Sierra Leone), which are less efficient and nonmigratory or less migratory.	2 Combined vector control and Ivermectin for 12 years projected to reduce disease to nonsignificant level. Ivermectin alone in areas of low CMFL (<10) where no invasion of *Simulium* threatens original OCP area.	2 Ivermectin throughout for extended periods up to 20 years as ivermectin does not interrupt transmission.	
3 Non-OCP countries: East of Benin to Sudan.		3 Ivermectin through community-based distribution systems.	3 Impact of ivermectin on skin disease and other manifestations of *O. volvulus* infection to be assessed.	
4 West and Equatorial Africa: Guinea-Bissau to Gabon; Rain forest.		4 Ivermectin through community-based distribution systems.		
5 Zaire Basin.		5 Ivermectin through community-based distribution systems.		
6 East Africa highlands: Ethiopia to Southern Malawi.		6 Focal vector control could achieve eradication of *S. damnosum* or *S. neavei*. Ivermectin through community-based distribution systems.		

(*Continued over*)

Tabl 8 *Stratification of epidemiology and control of onchocerciasis (Continued)*

Geographical locality	Epidemiological characteristics	Operational approach	Disease management	Prevention
Central America				
Guatemala; Mexico in well defined foci. Cross-border movement of migrant workers may spread the disease.	Anthrophilic *S. ochraceum* in highland foci; *S. metallicum* more zoophilic also involved. Inefficient as vector due to buccal armature: but compensated by vector abundance.	Control by ivermectin distribution via national programs through twice-yearly distribution.	Ivermectin-based.	Ivermectin distribution over years will reduce morbidity of skin and anterior segment eye disease
South America				
1 Brazil, S. Venezuela	1 Primary vectors: *S. oyapockense* and *S. guianense*. Secondary vector: *S. exiguum*.	Vector control not feasible. Integration of ivermectin with other programs.	Ivermectin-based.	Ivermectin distribution over years will reduce morbidity of skin and anterior segment eye disease.
2 N. Venezuela	2 Primary vector: *S. metallicum*. Secondary vector: *S. exiguum*.			
3 Ecuador, Columbia.	3 Primary vector: *S. exiguum*.			
Yemen				
Distributed along Wadis.	Vector: member of the *S. damnosum* complex (*S. rasyani*)	Ivermectin-based control initiated.	Ivermectin.	Ivermectin control embarked on.

Table 9 *Stratification of epidemiology and control of lymphatic filariasis (LF) (see Molyneux and Zagaria 2002)*

Geographical locality	Epidemiological characteristics	Operational approach	Disease management	Prevention
Tropical America: N E Brazil, Guyana, Surinam, French Guyana, Haiti, Dominican Republic, Costa Rica, Trinidad and Tobago.	Focal transmission by *Culex quinquefasciatus*. Varying levels of endemicity: Guyana endemic and about to launch program based on DEC salt. Haiti and Dominican Republic using DEC + albendazole. Surinam, Trinidad and Tobago, and Costa Rica have eliminated public health problem by DEC selective treatment	Limited control programs organized through Ministry of Health (in Brazil SUCAM). Urban mosquito control difficult. Strategy based on annual DEC + albendazole treatment of all eligible population. Introduction of home care for lymphedema	Opportunities for introduction of new approaches. Treatment using topical antibiotics, daily washing with soap and water of affected limbs thorough interdigital drying, limb elevation, and breathing. Single annual dose DEC + albendazole donated by GlaxoSmithKline	Very limited control implemented except in Recife. Potential for all appropriate measures to reduce transmission by single annual treatment of DEC + albendazole or DEC salt.
Tropical Africa: broad transmission zone in sub-Saharan Africa.	Urban filariasis *Culex quinquefasciatus* transmitted in E. Africa and Madagascar. Filariasis transmitted by *A. gambiae* complex and *A. funestus* in E. Africa and W. Africa. Mapping ongoing elsewhere to define implementation units for national control programs	Up-scaling control programs; nine countries active. Strategy based on ivermectin + albendazole where onchocerciasis and filariasis are co-endemic. DEC + albendazole elsewhere (Kenya, Zanzibar and Comoros).	Disease problems have been underestimated; hydrocoele surgery significant burden on district hospitals (30 percent of surgical interventions). Increase the development of home-based lymphedema management.	Pilot projects in Zanzibar using polystyrene beads for larval *Culex* control; impregnated bednets and, in urban areas, *Bacillus sphaericus* larval toxins. Development lingages and evaluate bednet programs on LF as part of malaria control.
Middle-East: Egypt	Urban and peri-urban transmission in Cairo and Nile delta. Resurgence since control relaxed in 1965 resulting in prevalence of c. 20 percent. *Culex molestus* and *C. quinquefasciatus* vectors.	DEC + albendazole campaigns active in all endemic villages in the Nile Delta (at-risk population 2.4 million) three rounds of drug distribution completed by end 2002. Vector control limited.	As above	Vector control likely to have limited impact; chemotherapeutic preventive approach will reduce transmission
Indian sub-continent: South Asia, India, Sri Lanka, Bangladesh, Nepal, Vietnam, Thailand, Myanmar.	*C. quinquefasciatus*, *Anopheles* species. Urban and semi-urban with high clinical morbidity particularly in India.	Variable depending on country and resources available. Chemotherapy via DEC + albendazole or DEC fortified salt. Mosquito control of limited impact.	As above. Surgery for serious deformities widely practiced in India, especially for hydrocoele, to reduce morbidity. Heavy cost burden on surgical services.	Mosquito control measures of limited impact. Define impact of DEC + albendazole on morbidity

(*Continued over*)

Table 9 *Stratification of epidemiology and control of lymphatic filariasisLF (see Molyneux and Zagaria 2002) (Continued)*

Geographical locality	Epidemiological characteristics	Operational approach	Disease management	Prevention
Pacific rim and islands	*Aedes* vector on Pacific islands. *Anopheles punctulatus* in Papua New Guinea, Vanuatu. *C. quinquefasciatus* in China. In the Solomon Islands *W. bancrofti* eliminated by malaria vector control in 1970s.	DEC + albendazole once a year for at least 5 years	As above.	Vector control difficult although some success in trials with *B. sphaericus* biocides. DEC salt and DEC + albendazole. Bednets contribute to reducing transmission in *Anopheles* settings (e.g. Vanuatu). Solomon Islands remain LF-free after elimination by indoor spraying of DDT in antimalaria campaign in 1980s
South Asia, India, Malaysia, Indonesia, China, Philippines, Vietnam. *Brugia malayi*, *Brugia timori*	*Mansonia*, *Anopheles*. In some areas animal reservoirs exist (cats and *Presbytis*, leaf monkeys).	Community participation in environmental vector control (weeding and fish culture) and chemotherapeutic control in India; use of DEC + ivermectin and DEC salt in same manner as for *Wuchereria bancrofti* filariasis.	As above. Treatment using topical antibiotics, hygiene of infected limbs in Kerala, India to ameliorate acute episodes.	Chemical control against *Mansonia* difficult due to variable adult behavior and larval association with weeds (dependence on environmental control).

Table 10 *Stratification of epidemiology and control of schistosomiasis*

Geographical locality	Epidemiological features	Operational approach	Disease and management	Prevention
Africa, South America, and Caribbean				
Schistosoma mansoni, *S. haematobium* widespread in Africa. *S. intercalatum* is limited in West and Central Africa. *S. mansoni* in South America and Caribbean	*S. mansoni/Biomphalaria* transmitted. *S. haematobium/ Bulinus* transmitted. *S. mansoni* has peak prevalence in 10–24-year-olds; heaviest parasite loads 10–14 age group. *S. haematobium* peak prevalence and intensity 10–14-year-olds.	Linkage to other sectors in planning prevention and control via appropriate water-resource management. Population movement to be monitored in context of potential disease impact after exposure to new water-related development. Development of link to schools for chemotherapeutic control and for health education. Assessment of potential for molluscicide.	Can result in significant morbidity and mortality, placing considerable burden on curative services. Severity of symptoms generally depends on intensity of infection. *S. mansoni* symptoms associated with hepatic, splenic, and intestinal systems. *S. haematobium* pathology concentrated in genital and urinary systems and lower intestine. Use of hematuria as rapid assessment tool for intervention priority.	Primary prevention is reduce access to contaminated water via improved management of water resources; involvement of other sectors in planning development projects. Chemotherapy assists in reducing infection reservoir; snail control may supplement control operations and be planned into irrigation schemes or impoundments. Health education via schools and community health providers. Maintenance of drug availability.
Middle East/North Africa				
S. mansoni and *S. haematobium*.			Praziquantel can reverse symptoms of severe disease. Carcinomas associated with schistosomal disease but precise etiology not established.	
South East Asia, China, Philippines, Thailand				
S. japonicum, *S. mekongi* in Kampuchea Laos.	*S. japonicum* transmitted by amphibious *Oncomelania* with many animal hosts (cattle, dogs, rats, pigs). *S. japonicum* has no typical age prevalence or intensity; variable depending on epidemiology. *S. mekongi* transmitted by *Neotricula* snails (dog reservoir).	National programs in China developed via communist structures in integrating chemotherapy and snail control. In Philippines, approaches to control through snail control, case detection and treatment, environmental sanitation, and health education. Redirection with increased emphasis with availability of praziquantel.	*S. japonicum* disease similar to *S. mansoni* with most severe disease between ages 2 and 40. Praziquantel effective in treatment.	

Operational phases of control operations: Phase 1 – planning data gathering; planning; resource allocation. Phase 2 – attack/intervention. Phase 3 – maintenance.

Table 11 *Recent epidemics of parasitic diseases, causes, impact and control*

Disease and geographical location	Putative cause	Epidemiological impact	Control problems and approaches
Malaria			
Madagascar, Highland malaria in Ethiopia, Kenya.	Change in agricultural patterns, interruption of control, environmental degradation (changing larval habitats), resettlement schemes , temperature change, and increased rainfall following period of drought. Non-immune population.	Over 25 000 deaths in Madagascar in 1988.	Institute epidemic preparedness policy. Ensure availability of appropriate drugs.
Forest-fringe malaria in South East Asia, South America.	Penetration into forest for gem and gold mining. Non-immune population exposed.	Epidemics in N.E. Kenya in 1999 following El Niño rains	Establish vector-control capacity and acquire insecticides.
Refugee camps.	New breeding sites; non-immune populations move to lower altitudes (e.g. Rwanda).		Inform and support local health structures and NGDOs.
Leishmaniasis			
Visceral leishmaniasis in South Sudan.	Ecological changes provide enhanced breeding sites for *P. orientalis* in *Acacia/ Balanites* woodland.	5 000 cases/year; 100 000 at risk – 75 percent mortality in children reported.	NGO-initiated treatment centers. Provision of emergency drugs. Limited diagnostic facilities. High incidence of post-kala azar dermal leishmanoid PKDL. Treatment established. Availability of drugs problematic.
Cutaneous leishmaniasis in Khartoum.	Population movement and breakdown of health services in conflict zone.	Outbreaks in Khartoum with 100 000 cases due to *L. major*.	Chemotherapy; vector control; rodent control.
Cutaneous leishmaniasis in Kabul, Afghanistan.	Lack of diagnostic capacity, drugs, and means of delivery.	New urban foci of transmission in *P. sergenti*. 4 000 cases in urban areas and 6 000 from provinces.	Active case detection and treatment; insecticide treatment of houses in cities; health education units.
Trypanosomiasis			
T. b. rhodesiense epidemic in Busoga, Uganda.	Change in ecology due to encroachment of *Lantana* following civil disturbance and change agricultural practices.	Up to 8 000 cases/year in 1980.	Surveillance and treatment. Establishment of treatment centers. Vector control via impregnated traps.
T. b. gambiense in Zaire–South Sudan, Angola	Breakdown of surveillance through disruption of health services.	Increased incidence.	Increase surveillance and treatment but coverage limited, drugs not available.
Schistosomiasis			
S. haematobium and *S. mansoni* epidemics increase associated with water-impoundment and rice irrigation throughout Africa.	Non-immune migrant population exposed for first time. *Bulinus senegalensis* breeds in irrigation systems; increase in snail populations. *Biomphalaria* increases. Major dam projects (Aswan, Egypt; Diama, Senegal and Akosombo, Ghana) are a well-recognized cause but micro-dams in West Africa provide additional and extensive new problems. War and refugee migration.	Increased incidence, high morbidity in non-immune populations.	Increase availability of chemotherapy. Target if possible through schools. Snail control or environmental management if feasible. Health education.

Table 12 *Widely used tools for parasitic disease control – diagnostics*

	Diagnostic tools		
Disease	**Personal diagnostic test (direct)**	**Personal diagnostic test (indirect)**	**Community assessment**
American trypanosomiasis		Serodiagnostic test using synthetic peptides.	Agglutination test for blood bank screening.
Dracunculiasis	Direct observation of worm emergence.		Use of village volunteers to identify cases and contain them.
Food-borne trematode infections	Kato technique (i.e. cellophane-fecal thick smear).	Intradermal screening for paragonimiasis.	
Leishmaniasis	Cutaneous: parasitological diagnosis by smear, culture.	ELISA immunofluorescence.	
	Visceral: parasitological diagnosis by bone-marrow puncture, spleen aspiration.	DAT.	
Lymphatic filariasis	Night blood films for nocturnally periodic forms; day blood films for diurnally periodic forms.	Assays to detect circulating filarial antigen by immunochromatographic test. 'Brugia Rapid' has similar characteristics for *Brugia*.	Hydrocoele survey; questionnaires to district hospitals for records; community assessment of lymphoedema rates.
Taeniasis, cysticercosis, neurocysticercosis	Fecal smear.	Coproantigen detection; CAT scan; NMR scan.	High prevalence of late-onset epilepsy; local pig husbandry, meat inspection, contaminated carcass detection.
Loa loa	Day blood films, presence of tropical eye worm or Calabar swelling.	No immunological methods available.	RAPLOA; use of remote sensing to determine areas of risk of high prevalence.
Malaria	Light-microscopic examination of Giemsa-stained blood films.	See Malaria.	
Onchocerciasis	Skin snips.	DEC patch test as methodology for rapid diagnosis (mini Mazzotti).	Rapid assessment of nodule prevalence.
Schistosomiasis	Kato technique for: *S. intercalatum*, *S. japonicum*, and *S. mansoni*.	Quantitative urine filtration technique for *S. haematobium*.	Direct observation for gross hematuria, indicative of heavy *S. haematobium* infection in children in endemic areas.
			Detection of microhematuria by reagent strips (*S. haematobium*).
Sleeping sickness	Blood film.	Lymph gland palpation.	
	CSF examination.	CATT.	
	Bone-marrow aspiration.	Capillary tube centrifugation.	

Table 13 *Widely used tools for parasitic disease control – chemotherapy*

Disease	Treatment tools		
American trypanosomiasis	Acute phase: nifurtimox.	Blood bank transmission control: crystal violet/sodium ascorbate to kill parasites in infected blood.	
Dracunculiasis	Treatment aimed only at superinfections.		
Food-borne trematode infections	Praziquantel.		
Leishmaniasis	Pentavalent antimonials.	Amphotericin B.	Pentamidine.
Lymphatic filariasis	DEC + albendazole outside areas of onchocerciasis endemicity.	Ivermectin + albendazole in onchocerciasis-endemic areas.	
Malaria	Sporontocidal: proguanil, pyrimethamine, atovaquone. Tissue schizontocidal: primaquine, proguanil, tetracycline. Gametocytocidal: primaquine, quinine, mefloquine, chloroquine, amodiaquine. Blood schizontocidal: quinine, mefloquine, halofantin, chloroquinine, amodiaquine, atovaquone, artemisinins, pyronaridine, tetracycline.	Sulfadoxine/pyrimethamine or sulfalene/pyrimethamine, mefloquine.	Severe disease: quinine (+ tetracycline where needed). Artemether where quinine resistance.
Onchocerciasis	Ivermectin (single dose mass administration once a year). In the Americas, twice yearly treatment given.		
Schistosomiasis	Praziquantel.	Metrifonate.	Oxamniquine.
Sleeping sickness	Early stage: pentamidine (*T. b. gambiense*). Suramin (*T. b. rhodesiense*).	Advanced stage: melarsoprol for both forms. Eflornithine if available for melarsoprol-resistant cases of *T. b. gambiense*.	For arsenical-resistant cases of *T. b. gambiense* (mainly): eflornithine; nifurtimox has been produced for drug-resistant cases on humanitarian grounds.
Taeniasis, cysticercosis, neurocysticercosis	Praziquental for *T. solium*.	Praziquental given as mass chemotherapy can reduce prevalence of cysticercosis.	

Table 14 *Widely used tools for parasitic disease control – vector control*

Disease	Vector control tools		
American trypanosomiasis	Indoor residual spraying with pyrethroids.	Pyrethroid paint.	Fumigant canisters with pyrethroids.
Dracunculiasis	Temephos.		
Food-borne trematode infections	Environmental management, including land reclamation and drainage.	Niclosamide (molluscicide).	Biological control (natural predators).
Leishmaniasis	Residual insecticide spraying (DDT, pyrethroids).	Insecticide-treated nets have impact where transmission is in houses (Middle East *L. tropica* urban foci and in South America).	Insecticide-impregnated collars for dogs, which are reservoir hosts of *L. infantum* (Gavgani et al. 2002).
Lymphatic filariasis	Impregnated bednets in areas where disease is transmitted by *Anopheles*.	Polystyrene beads (if feasible) in settings where disease is transmitted by *Culex*; integrated control in Pacific where dengue control for *Aedes* is implemented.	Pyrethroid-impregnated bednets and curtains.
Malaria	Pyrethroid-impregnated bednets and curtains.	Indoor residual spraying (DDT, organophosphates, carbamates, pyrethroids).	Environmental management.
Onchocerciasis	Larviciding though aerial spraying (in rotational use: *B.t* H-14, temephos, pyraclofos, pyrethroids).	Ground larviciding employed in some settings where access is easy; *Simulium neavei* eliminated from several areas of East Africa by larvicides; deforestation reduces *S. neavei* populations.	
Schistosomiasis	Niclosamide (molluscicide).	Environmental management of irrigation systems.	
Sleeping sickness	Pyrethroid-impregnated screens.	Traps; pyrethroid-impregnated and non-impregnated.	

Table 15 *Examples of changes in* Plasmodium falciparum *:* P. vivax *ratios associated with anthropogenic change (conflict, irrigation, mining)*

Location	Projected changes	Reference
Tajikistan	Health systems disruption, conflict migration, chloroquine resistance in *P. falciparum*.	Pitt et al. (1998)
Afghanistan/Pakistan	Chloroquine resistance in *P. falciparum*.	Rowland and Nosten (2001)
Sri Lanka, Mahaweli	Irrigation on large scale.	Amerasinghe and Indrajith, 1994
Thar Desert, Rajasthan, India	Irrigation on large scale. Establishment of *Anopheles culcifacies* as efficient *P. falciparum* vector and dominance over *An. stephensi* (a poor vector).	Tyagi and Chaudhary (1997)
Amazonia, Brazil	New breeding sites for efficient vectors *An. darlingi* through mining, deforestation, road building.	Marques (1987)

Diagnosis of parasitic infections

STEPHEN H. GILLESPIE

Introduction	1	Molecular diagnosis	7
Specimens	3	References	8
Immunological diagnosis	6		

INTRODUCTION

The ubiquity of human parasites is such that their diagnosis should be of importance to all involved in the management of patients with infection. Yet this branch of diagnostic microbiology is often strangely neglected. Parasite diagnosis frequently poses unique problems requiring novel solutions. The diversity of agents requires, on the part of the diagnostician, an encyclopedic knowledge covering pathogens that are imported and genuinely rare. Also, it requires the application of the full range of microbiological diagnostic methods. The majority of parasite diagnoses are made in a laboratory whose major interest is bacteriology but there are a number of important differences in the approach required for success. This chapter outlines the factors necessary for successful diagnosis of parasitic infections.

Life-cycle and natural history

Humans often form only one part of a complex parasitic life cycle. It is important to understand the way in which the organisms interact with the host if optimal diagnosis is to be obtained. For example, *Toxocara canis* is the ascarid parasite of canids and is unable to complete its life cycle in humans and other paratenic hosts (Gillespie et al. 1993). The diagnosis can be made in canids by examining stools for the presence of the characteristic eggs (Habluetzel et al. 2003). In contrast, in paratenic hosts such as the human, this approach will fail because parasite development is blocked at the L2 larval stage and adults cannot be found in the stool; it is thus essential to diagnose this infection by serological means.

Giardia has a simple life cycle which may only involve humans (and potentially an animal reservoir). The diagnosis is made simply by examining stools for the presence of *Giardia* cysts. However, a proportion of cases may not be diagnosed by this means and symptoms consistent with giardiasis may persist. In this instance, the fact that the protozoa preferentially infect the duodenal–jejunal junction means that this site can be sampled directly, either by duodenoscopy and biopsy or by the string test (see String test below).

Knowledge of the life cycle and natural history can indicate when to sample. For example, patients who have been exposed to schistosomiasis by swimming in contaminated water may present soon after their return from an endemic country. They may already have the symptoms and signs of Katayama fever. However, it would be futile to attempt to make a diagnosis by microscopic examination of stool or urine as it is likely that adults will not have matured and begun to deposit eggs. Later in the infection, the excretion of eggs may not be regular: in *Schistosoma haematobium* infection, eggs are preferentially excreted around mid-day. To obtain maximum yield, urine should be collected at this time. Similar considerations apply to the diagnosis of filarial infections where these parasites have become adapted to the circadian rhythms of the host. In areas where mosquitoes are night-biting, the maximum diagnostic yield can be obtained by sampling between midnight and 2 a.m. (Simonsen et al. 1997).

The pathogenic mechanisms of the parasite may affect the choice of specimen. *Plasmodium falciparum* produces knobs on the surface of the red cell that make it adhere to capillary endothelium, a point of considerable importance in the pathogenesis of cerebral

malaria (Waller et al. 1999). It also has importance for laboratory diagnosis as capillary blood has a higher diagnostic yield than the venous blood traditionally sampled by doctors in developed countries. The microfilariae of *Onchocerca volvulus* can be found in the skin, but their distribution is not uniform. Knowledge of the normal distribution of microfilariae and the variations in different geographical locations will increase the diagnostic yield and reduce the number of (painful) pinch biopsies required to make a diagnosis (Scheiber et al., 1976).

Resources

The world is ill-divided, especially when it comes to infectious diseases. The poorest members of the world community have a disproportionate number of the world's parasites. Thus, those with the greatest need of parasite diagnosis have the least economic resource to acquire it (World Bank 1993). This financial fact of life is one that those charged with parasite diagnosis must bear in mind in delivering diagnostic services. It means that resources should be targeted on the most important clinical problems. For example, concentration techniques increase the yield of positive results for protozoal cysts and helminth eggs, but the cost of reagents and the expense of purchase and maintenance of a centrifuge may mean that simple wet preparations should be employed (Ramsay et al. 1991). Such compromises may not be as damaging as a superficial assessment might suggest. For individuals living in an endemic area and constantly at risk of acquiring infection, sensitive diagnosis may result in many treatment courses where the balance of benefit between parasite clearance and drug adverse events is uncertain.

The same considerations must be made in relation to technology. A range of diagnostic approaches can be applied to protozoa and helminths, but many of these methods are too expensive to be applied in the areas where the infections are most common.

Objectives of parasitic diagnosis

PATIENTS FROM NON-ENDEMIC AREAS

Many individuals now travel to countries where tropical parasites are endemic. Returning travelers will have some clear diagnostic demands. They may be very concerned about the risk of tropical parasites, no doubt enhanced by lurid stories from hardened expatriates. Their objective in presenting for diagnosis is to exclude the risk of an infection which is not yet causing symptoms (MacLean and Libman 1998). It may be that such a disease is evolving but the traveler is presenting before the infection has had time to become patent. Moreover, as infections in travelers are often light, the disease may present in a more subtle way than that described in the textbooks of parasitology and tropical medicine.

Travelers often lack the immunity that inhabitants of endemic countries possess. This may have a significant impact on the natural history of infection and a change in the speed at which diagnosis is required. *P. falciparum* is rapidly progressive in immunologically naïve subjects. Thus, when malaria is suspected in such a patient, the diagnosis of malaria should be made rapidly.

Patients from an endemic country with *Entamoeba* cysts in their stool rarely need further investigation. However, for a patient living in a country where this disease is rare, it would be useful if a species-specific diagnosis could be made. It is normal practice to attempt to eradicate cyst passage in returning travelers. To prevent unnecessary treatment in patients with *Entamoeba dispar* infection, a species-specific diagnosis is required (Sanchez-Guillen et al. 2002).

PATIENTS IN ENDEMIC AREAS

Most health facilities in endemic areas experience a severe shortage of resources for medical services. These scarce resources are often disproportionately directed towards clinical services. This frequently means that laboratories charged with the task of making a diagnosis lack the necessary resources to do so. Hospital managers often do not recognize that resources spent in obtaining an accurate diagnosis may produce savings in medical and pharmacy costs. Faced with this, it is essential that laboratory managers choose wisely which diseases to target and which methods to employ. Many patients have had to travel long distances to access healthcare. This means that, where possible, methods should be employed that provide a rapid diagnosis. The patients are now often required to make a financial contribution towards the cost of their laboratory costs and this may also serve to limit the scope of testing. These considerations do not necessarily mean that a poor quality service is the inevitable result. Although recent diagnostic developments have achieved similar sensitivity and specificity as a thin blood film examined by a trained microscopist, the latter remains the optimum diagnostic method for most parts of the world (Humar et al. 1997). Also, although limited resources probably limit stool examination to a direct saline wet preparation, this method will reliably diagnose the individuals that are most heavily infected with helminths and are thus most likely to benefit from treatment (Ramsay et al. 1991).

DIAGNOSIS FOR PUBLIC HEALTH

The approach to diagnosis required for public health purposes is often very different from that for routine curative services. In many instances, the questions posed are quite dissimilar and this has an impact on the methods employed. For example, for a patient who is thought to have schistosomiasis, the identification of a single egg in stool or urine is all that is required to initiate therapy. However, in a schistosomiasis control

program, although this sort of result will be useful in quantifying the number of patients with infection, it is more likely that it will be necessary to quantify the worm burden of people living in infected communities. Thus, for *S. mansoni* infections, it would be necessary to perform a Kato-Katz investigation that would give a useful estimate of the number of eggs per gram, and thus the overall worm burden (Katz et al. 1972). To characterize the nature of hookworm infection, culture is necessary but this would have no impact on the management of the patient's illness (Harada and Mori 1955). In addition, parasite field studies often need to process specimens from a very large number of patients in a short time and methods must be adapted to this requirement.

Serology has limited value in the diagnosis of parasitic infections in endemic areas, but serological techniques are often employed in public health surveys as a way of rapidly determining the number of patients who have current or past infection with a particular pathogen.

In determining the epidemiology or epizoology of parasitic infections, it may be necessary to employ complex typing techniques to characterize pathogens identified in different communities. For example, the identification of a species of *Leishmania* might be sought so that its method of transmission could be better understood for control purposes. To achieve this, microsatellite DNA analysis and multilocus enzyme electrophoresis can be employed (Banuls et al. 2002; Barker 2002). Such techniques are not required for diagnosis in routine practice.

DIAGNOSIS FOR RESEARCH

Good-quality field research of parasitic infection should ask a very specific question for which diagnostic methods may be required. For example, if the nature of drug-resistant malaria is under investigation, it might be necessary to deploy DNA amplification techniques to determine the presence of various drug-resistance genes (Dorsey et al. 2001).

SPECIMENS

Any tissue or body fluid can be used for the diagnosis of parasitic infections. However, it is essential that the right specimen is obtained for diagnosis and in the right condition. It is pointless to spend time searching a stool for the presence of amebic trophozoites unless the stool is both fluid and fresh: amebic trophozoites rapidly lose motility as the temperature falls. Although females of *Trichinella spiralis* are found in the intestine and produce symptoms of diarrhea, the diagnosis of trichinosis is made by serology or by the examination of a muscle biopsy (see *Trichinella*).

Stool samples

A minimum of three samples of stool is necessary to make a diagnosis of intestinal infection. As excretion of parasite eggs and cysts can be intermittent, it is preferable that specimens be sent on different days. To identify the trophozoite stage of *Entamoeba* and *Giardia*, freshly passed stools should be examined. If this is not possible, it may be necessary to fix the specimen for later examination. It may not be possible to make a diagnosis of amebiasis from a stool sample but motile trophozoites may be observed in scrapings from intestinal ulcers visualized on sigmoidoscopy.

Duodenal/jejunal biopsy or Enterotest may be needed to sample the jejunal fluid to diagnose giardiasis (Goldsmid and Davies 1978). A summary of the parasites that can be diagnosed using intestinal samples is listed in Table 1. Each of the modalities of laboratory diagnosis may need to be employed.

MACROSCOPIC EXAMINATION

It is essential to note the consistency of the stool to be examined. This can guide the technologist as to whether or not there is purpose in trying to identify trophozoites

Table 1 *Methods and pathogens that can be identified in intestinal specimens using these methods*

Sample	Method	Examples of pathogens identified
Stool	Microscopic examination of unstained and stained preparations	Protozoa: *Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium parvum*, *Isospora belli*, Microsporidia
		Helminths: *Trichuris trichiura*, hookworms, *Ascaris lumbricoides*, *Schistosoma* spp.
	EIA, nucleic acid amplification	*Cryptosporidium parvum*, *E. histolytica*, *G. lamblia*
	Culture	*Strongyloides stercoralis*, speciation of hookworm
Adhesive tape sample, anal swab	Direct microscopy	*Enterobius vermicularis*
String test, duodenal fluid examination	Microscopy, EIA PCR	*G. lamblia*, *Cryptosporidium parvum*, *S. stercoralis*
Sigmoidoscopy	Direct examination and ulcer scrapings	*E. histolytica*
Proctoscopy	Rectal biopsy	*Schistosoma mansoni*

or cysts. Also, a negative result is often more easily explained to a clinician suspecting diarrheal disease if the fact that the stool is formed is noted. The presence of proglottids can be confirmed by macroscopic examination of the stool and sometimes adult ascarid worms can be found in stools.

MICROSCOPIC EXAMINATION

Direct saline wet preparations have the virtue of speed and cheapness. Unfortunately, this method of examination is less sensitive than the concentration techniques. Direct saline preparations are required if the trophozoite stages are to be seen. Quantification of the number of eggs present in stools may be achieved by variants of the Kato-Katz method (Katz et al. 1972).

Staining of stools can improve the diagnostic yield by making the target pathogen more easy to identify. Modified acid fast preparations or the use of UV illumination for the examination of auramine-stained preparations make the identification of *Cryptosporidium* and *Isospora* much easier (see Intestinal coccidia: Cryptosporidiosis, isosporiasis, cyclosporiasis). In the same way, modified trichrome, Starey-Warthin, and calcofluor white may assist the diagnosis of microsporidiosis (see Microsporidiasis). Rapid specific diagnosis can be obtained by the use of direct immunofluorescence (Kuczynska et al. 2003). For the diagnosis of microsporidiosis, direct immunofluorescence is probably essential. These techniques have proved of particular value for the diagnosis and quantification of intestinal protozoa in water supplies.

To improve the sensitivity of diagnosis, stools should be concentrated. A wide variety of methods is reported in the literature. Many of these methhods require expensive reagents and equipment such as a centrifuge, but others have been adapted for resource-poor communities (Ramsay et al. 1991). Different techniques are required for different pathogens and the optimal method should be employed for any specific target pathogen in, for example, a research study. To overcome the need to employ more than one concentration method, many laboratories choose to use an all-purpose method that gives good all-round performance. The formol–ether method and its variants are widely used as they provide good concentration of protozoal cysts and helminth eggs while also removing fecal debris (Allen and Ridley 1970). Commercially prepared centrifugation tubes can make this technique easier to apply.

IMMUNOLOGICAL AND MOLECULAR DIAGNOSTICS

Enzyme immunoassays can also be used to process stool samples. These methods have the advantage that they can be automated. Commercially produced diagnostic tests are now available for most intestinal protozoan pathogens (Garcia et al. 2000). In the same way, primer pairs for the main intestinal protozoa are now available and provide enhanced sensitivity. With the appearance of real-time polymerase chain reaction (PCR) equipment, it is now possible to make a rapid specific diagnosis of intestinal protozoal infections using these techniques (Bialek et al. 2002).

CULTURE METHODS

One of the major differences between parasitology and most other branches of microbiology is the fact that culture methods are rarely used. However, there are a limited number of situations where cultures of parasites are essential for a complete diagnosis. *Strongyloides* larvae are difficult to identify in stools, and an improved yield can be obtained by culturing stools. Cultures can reveal the presence of larvae when their numbers are low (Arakaki et al. 1990). Culture is also essential to permit species identification of hookworms (Harada and Mori 1955).

The viability of schistosome eggs can be determined by microscopic examination to see the cilia of the 'flame' cell. Alternatively, it is possible to hatch the miracidium from the eggs – the ultimate proof of viability. Fresh stool or urine specimens are placed in ten volumes of unchlorinated water (e.g. spring water) in an Erlenmeyer flask. The flask is covered and the sediment examined after 24 hours for the presence of miracidia.

SIGMOIDOSCOPY

The value of ulcer scrapings for diagnosis of amebiasis has already been discussed. In addition to this, rectal biopsy samples obtained at sigmoidoscopy or proctoscopy can be valuable in the diagnosis of schistosomiasis, especially in travelers when the number of eggs present in stools may be small (Harries et al. 1986).

STRING TEST

This technique depends on a length of nylon 'string' with a weighted end. This is swallowed and travels to the upper part of the jejunum. After a period of time, the string is pulled up and the fluid expressed can be examined. Bile-staining of the string can be read as proof that the string has traveled as far as the jejunum. Commercial versions of this device are available and the method can be used to make a diagnosis of giardiasis, strongyloidiasis, and cryptosporidiosis (Beal et al. 1970).

PINWORM

Pinworms, *Enterobius vermicularis*, lay their eggs on the skin around the anus. The optimum diagnostic yield is obtained from the perianal skin. Eggs can be harvested by using adhesive cellulose tape and then examined microscopically. Several commercial kits are available that make the diagnosis of pinworm more easy (Wagner and Eby 1983).

Urogenital samples

MACROSCOPIC EXAMINATION

Urine should be examined macroscopically where overt hematuria associated with urinary schistosomiasis can be observed. In cases of lymphatic filariasis, abnormal connections between the thoracic duct and ureters can permit leakage of lymph into the urine. This phenomenon, chyluria, is demonstrated by the excretion of milky urine after the patient has taken a fatty meal.

MICROSCOPIC EXAMINATION

Eggs of *Schistosoma haematobium* are mainly excreted into the urine were they can be demonstrated by microscopic examination. It is possible to improve the sensitivity of the method by expressing a larger volume of urine through a micropore membrane. Eggs are trapped in the membrane and can be seen under the microscope. An estimation of the worm burden can be obtained for research purposes by filtering a standard volume, usually 10 ml (Peters et al. 1976).

The diagnosis of vaginitis or urethritis caused by *Trichomonas vaginalis* is usually made by examination of vaginal discharge fluid or urethral pus. A simple saline wet preparation may permit the observation of the characteristic motile protozoa (see Figure 13.1, p. 256). Diagnosis can be made more sensitive by the use of direct immunofluoresence and culture (Draper et al. 1993).

CULTURE

Urine from patients infected with *S. haematobium* can be incubated overnight and the sediment observed for the presence of viable miracidia. The diagnosis of trichomoniasis can be enhanced by culture of vaginal and urethral secretions (see *Trichomonas* infections).

Blood

Blood is a vital specimen for the diagnosis of parasitic infections because many organism have a blood stage as part of their life cycle. These are summarized in Table 2. It is essential that the specimens are taken at the right time. Malaria parasites are characteristically detectable in the blood during a fever and for some hours afterward. When a patient presents with fever and a history of residence or travel in an endemic area, it is essential to take a blood film for malaria immediately; however, a minimum of three samples should be obtained when the patient is febrile. Failure to follow this rule may result in a false negative diagnosis. In cases of lymphatic filariasis, there is diurnal variation in the presence microfilariae in blood. For this reason, it is essential to obtain blood samples at the correct time and to take the samples into bottles containing ethylenediaminetetraacetic acid (EDTA) (Simonsen et al. 1997).

CONCENTRATION TECHNIQUES

Many parasites may be present in blood in low numbers, which makes concentration techniques essential. The simplest of these is the thick film: red cells stacked on top each other are lysed by the hypotonic Field's stain – this allows a large number of red cells to be scanned quickly for the presence of the characteristic ring-shaped merozoites of malaria parasites. Centrifugation and fluorescence microscopy can be used to enhance the sensitivity of diagnosis. Using fluorescent antibodies makes this technique more sensitive for the diagnosis of *P. falciparum* and *P. vivax* (Forney et al. 2003). Buffy-coat concentration may permit the diagnosis of *Leishmania donovani* and African trypanosomes (Woo 1970). An improved concentration technique for African trypanosomes is to centrifuge blood through a DEAE column (Lumsden et al. 1979). To concentrate microfilariae, a measured volume of blood can be filtered through a micropore membrane (Bell 1975; Desowitz et al. 1973). The membrane is then stained and examined microscopically to enable species identification. This approach has the dual advantage of increasing the sensitivity of the technique while permitting the numbers of organisms present to be counted.

CULTURE

There are few culture techniques for blood samples because most of the organisms require the intervention of intermediate vectors. However, specimens of blood and buffy coat can be cultured for *Leishmania* on media such as Schneider's insect medium. After two weeks, promastigotes can be visualized. The sensitivity of blood culture for *Trypanosoma cruzi* can be improved by

Table 2 *Protozoan and helminth parasites that can be identified in blood*

Specimen	Technique	Pathogens
Whole or EDTA blood	Thick and thin films	*Plasmodium* spp., *Leishmania donovani* and *L. infantum*, *Trypanosoma brucei rhodesiense* and *T. b . gambiense*. *Babesia* spp., various microfilaria
Buffy coat	Stained film	*Leishmania* spp., *Trypanosoma* spp., microfilariae
EDTA blood	DEAE concentration	Trypanosomes
	Membrane filtration	Microfilariae

xenodiagnosis. Uninfected triatomid bugs are permitted to feed on a suspected patient for approximately 30 minutes. The bugs are then kept and sacrificed monthly for 3 months. The guts are dissected and examined microscopically for the presence of trypanosomes.

Biopsy specimens

In many instances, the life-cycle of the parasite means that the only effective means of diagnosis is biopsy. For example, *Leishmania donovani* can be obtained from concentrated buffy coat cells but this is less sensitive than biopsy of bone marrow or splenic fluid where the organisms are concentrated. For many parasitic infections, biopsy is the only practical means of making the diagnosis (e.g. cutaneous leishmaniasis or onchocerciasis). A list of the most common parasitic infections diagnosed by biopsy is listed in Table 3.

SKIN

Punch biopsies or 'skin snips' are the investigation of choice for onchocerciasis. Specimens should be obtained from areas of skin that exhibit the characteristic dry 'chicken skin' appearance that has been associated with infection. In addition to any suspect areas, samples should be taken from the shoulder area, from the buttocks and from the calves even when the skin appears normal. The biopsies are then placed in saline for transport to the laboratory. The microfilariae start to emerge after 30 minutes to 1 hour and can be identified by their characteristic movement. In addition, stained preparations permit the identification of species. The diagnostic yield can be increased by giving the patient a small dose of diethylcarbamazine, which stimulates the migration of the microfilariae.

The diagnosis of cutaneous leishmaniasis depends on a biopsy of the suspected ulcer. Material can be obtained for microscopy or culture using a slit skin smear. A touch preparation from a biopsy of the ulcer edge can be made. Alternatively, the biopsy material can be cultured in Schneider's insect medium for 2 weeks.

MUSCLE

Trichenella spiralis larvae are located in the striated muscle. Diagnosis can be made by muscle biopsy and then pressing the material between two slides for examination under the microscope.

BRAIN

Biopsy of the brain may form part of the diagnostic process for a number of parasitic infections where various stages may be found in the brain. Biopsy may be performed to diagnose the etiology of ring-enhancing lesions in the brain demonstrated by computed tomography (CT) scans or magnetic resonance imaging (MRI). This situation often arises in patients with late stage human immunodeficieny virus (HIV) infection with low CD4 cell counts. The differential diagnosis includes lymphoma and cerebral toxoplasmosis. Other parasites that may be observed in brain biopsy include tissue stages of *Taenia solium*, *Echinococcus multilocularis*, *Entamoeba histolytica*, and eggs of various schistosomes.

IMMUNOLOGICAL DIAGNOSIS

Antibody detection

Immunological diagnosis is an attractive approach to parasitic diagnosis but has only established itself in a limited number of diagnostic areas. This is not surprising since the immune response to protozoan and metazoan pathogens is often complex and many of these organisms have evolved methods to subvert the immune response.

Table 3 *Summary of techniques and pathogens identified with biopsy specimens*

Specimen	Technique	Pathogen
Skin	Slit skin smear	*Leishmania* spp.
	Pinch biopsy	*Onchocerca volvulus*
Brain	Microscopic examination of stained smears, culture, EIA PCR	*Toxoplasma gondii*, *Naegleria fowleri*, *Acantamoeba*, microsporidia, cysticercosis, *Echinococcus* spp.,
Muscle	Direct microscopy	*Trichinella spiralis*
Eye	Microscopy of stained samples	Microsporidia, *Acanthamoeba*
Vitreous or aqueous	EIA	*Toxocara canis*
Lymph node	Microscopic examination of stained material	*Trypanosoma* spp., *Toxoplasma gondii*, *Leishmania donovani*
Liver	Microscopic examination of stained preparation	*Toxoplasma*, *Naegleria*, *Entamoeba histolytica*, Microsporidia, *Opisthorchis sinensis*
	Examination of cyst fluid by microscopy and EIA	*Echinococcus granulosus*
Bone marrow	Microscopy of stained material and culture	*Leishmania donovani* and other species

Patients in many tropical countries have raised concentrations of polyclonal, low-affinity antibody that tends to produce false positive results in many immunological tests. Also, patients in endemic countries have life-long exposure to pathogens and many have serological evidence of previous infection making it impossible to identify a new infection.

TOXOPLASMOSIS

Toxoplasmosis is one disease for which immunological diagnosis is the method of choice. Although the organism is relatively easy to culture for sufficiently sensitive diagnosis, animal inoculation is required and, therefore, this approach to investigation is limited to the processing of precious specimens. Evidence of recent toxoplasmosis can be demonstrated using the Sabin-Feldman dye test or one of many commercial assays to detect immunoglobulin (Ig)M (Sabin and Feldman 1948; Evans and Ho-Yen 2000). The age of the infection can also be determined by measuring the affinity of serum IgA.

AMEBIASIS

Antibodies to *E. histolytica* can be detected by a variety of techniques including indirect immunofluorescence assay (IFA) and indirect hemagglutination assay (IHA). These titers are often negative in patients with intestinal disease but are elevated in patients with invasive infection. Acute diagnosis of amebic abscess can be assisted by the use of the cellulose acetate precipitin test, which becomes positive much earlier than the IFA and IHA.

MIGRATING WORMS

Most of the organisms responsible for larval migration are unable to complete their life cycle in the human host. As a consequence, it may not be possible to identify these organisms by conventional phenotypic methods. An example of such a parasite is *Toxocara canis*; the diagnosis is made by detection of antibodies specific to the excretory secretory antigens (de Savigny et al., 1979). Other examples include *Trichinella*, dog hookworm infection, and gnathosomiasis.

RETURNING TRAVELERS

Although of little value in endemic countries, many serological tests are of diagnostic value in returning travelers because the time frame of their exposure to the infective agents is known. In addition, the degree of the infection is frequently light, which makes diagnosis by conventional morphological methods more difficult. As travelers are unlikely to have been exposed to organisms such as schistosomiasis or filariasis previously, the detection of antibodies to such parasites could be diagnostic. Alternatively, because many travelers seek medical help to exclude tropical infections, a negative result may be seen as even more valuable in that it allows the patient to be reassured.

EVALUATION OF SPACE-OCCUPYING LESIONS

Detection of antibodies to *T. solium*, *Echinococcus granulosis* and *Echinococcus multilocularis* may assist the difficult diagnosis of these infections. Several enzyme immunoassays (EIA) have been described (Feldman et al. 1990).

Antigen detection

Direct detection of parasite antigens, as opposed to the detection of antibody responses, has found a regular place in diagnosis.

MALARIA

A simple dipstick presentation kit is available for the rapid diagnosis of malaria. Although the cost of this kit may restrict its application in resource-poor countries, it does provide a rapid and reliable diagnosis of *P. falciparum* and *P. vivax* malaria without the need for a microscope or EIA reader. It is probably a little less sensitive than the results obtained by an expert microscopist. It is indicated for the rapid diagnosis of malaria in laboratories that do not process many specimens for malaria. It would allow a rapid reliable diagnosis that could be confirmed by a reference facility.

INTESTINAL PROTOZOA

Commercially produced kits with a IFA or EIA format are available for the diagnosis of *Giardia lamblia, Cryptosporidium parvum,* Microsporidia, and *Entamoeba histolytica* infection. The latter method is especially valuable as *E. histolytica* and *E. dispar* cannot be distinguished under the light microscope. These methods appear to be at least as sensitive as light microscopy and, if the EIA format is employed, also permit large numbers of specimens to be processed (Ong et al. 1996).

MOLECULAR DIAGNOSIS

Although many molecular diagnostic methods have been described, molecular diagnostics have little part to play in diagnosis for the majority of parasitic infections. However, they do have considerable application in public health microbiology and in research when it is necessary not only to identify the presence of a pathogen but also to determine its subtype. Molecular methods can also be used to investigate the mechanisms of resistance to antiparasitic drugs. This has proved especially valuable for malaria and for intestinal nematode infections.

DEFINITION OF THE CELL

The organic entities on Earth exist in the following forms: various types of cells; short sequences of stable proteins (prions); extracellular genomes (viroids, or naked RNA molecules); and protein capsules, or capsids, containing relatively short molecules of DNA or RNA often surrounded by an additional membrane (bacteriophages and viruses). Prions, viroids, phages, and viruses lack their own metabolism and the ability to reproduce independently, whereas all types of cells are true living systems with metabolic ability and the capacity for independent reproduction. All cells share the following common attributes:

- They are enclosed by a cell membrane.
- Their systems of reproduction use DNA for information storage and RNA for directing cellular organization.
- Their genomes may undergo accidental change (i.e. mutate).
- They can use chemical bond energy or light energy to run their metabolic systems.
- They can detect and respond to environmental signals and can receive, recognize, and transmit signals and impulses.

Cells may also be motile and, in the case of eukaryotes, may have flowing cytoplasm (Mehlhorn and Ruthmann 1992; Alberts et al. 2002; Hausmann et al. 2003).

Two basic types of true cells are distinguishable: prokaryotes and eukaryotes. There are no transitional forms in existence today, and thus these two forms are quite distinct. Prokaryotes always occur as functionally single cells with no specialization, whereas eukaryotes may consist of a single cell (e.g. Protozoa) or may be multicellular organisms made up of differentiated (specialized) cells (e.g. Metazoa). If prokaryotic organisms (such as mycoplasms and bacteria) do aggregate, they occur as chains or clusters of unspecialized cells. In contrast, eukaryotes can consist of many cells functioning in a highly integrated fashion. Some significant differences between the cellular components of eukaryotes and prokaryotes are listed in Table 1.

Prokaryotic and eukaryotic cells represent the units of life. It was recognized by Virchow in 1855 that they are the smallest units capable of maintaining the continuity of life or, as he expressed it in Latin, '*Omnis cellula e cellula*' (every cell derives from a cell).

UNICELLULAR EUKARYOTES

The higher protists (those that resemble plants, fungi, and animals) are all composed of eukaryotic cells. Eukaryotes may be unicellular in all their developmental stages, as are the protists, or unicellularity may be limited to certain developmental stages, such as the generative forms (the oocytes and spermatids) of plants and animals. Protists have followed many evolutionary

Table 1 *Differences between prokaryotes and eukaryotes*

Attributes	Prokaryotes	Eukaryotes
Cell nucleus		+
DNA		
Amount	Low (up to 1.4 $\times$ 10^{-2} pg/cell)	High (up to 1.6 $\times 10^{-2}$ – 96 pg/cell)
Organization	Circular	Linear (chromosomes) plus circular elements
Recombination	Conjugation	Meiosis and syngamy
Introns		+
Cell division		
Speed	Quick (20 min)	Slow (hours)
Mode	By formation of septa	By mitosis and cytokinesis
Organelles		
Ribosome type (subunits)	70S (30S + 50S)	80S (40S + 60S)
Membrane-bound organelles (mitochondria, plastids, Golgi, etc.)		+
Microtubules		+
Membrane-bound flagella (9 $\times$ 2 $\times$ 2 pattern)		+
Use of actomyosin for movement		+
Endo- and exocytotic activity (i.e. movement)		+

paths in the development towards multicellularity, and the following protists represent intermediate steps in this process:

- protist forms with many nuclei per cell
- stable, double nucleated forms, such as *Giardia*
- forms with cell aggregation including some green algae, like *Volvox*
- forms with chains of dividing organisms, e.g. microsporidians
- forms that have multicellular stages, e.g. Myxozoa.

Note that although the Myxozoa, or myxosporidians, have long been classified with the protists, and are mentioned here, it is now accepted that they should be classified with the Metazoa (see Cavalier-Smith 1998). Even highly differentiated Metazoa retain vestiges of their unicellular origin, as shown by their development from unicellular eggs, some of which may develop even if they are not fertilized. They also have the ability to reconstruct their whole bodies from a single cell, as do the sponges (phylum Porifera).

The group termed protists is comprised exclusively of unicellular eukaryotic organisms that may be phototrophic, autotrophic, or heterotrophic. The Protozoa are named after the Greek term for 'first' (*proto*) and 'animal' (*zoon*). They are heterotrophic, lacking the ability to use light and inorganic materials to obtain energy and to synthesize structural components. Therefore, they must obtain preformed organic compounds, and on this basis may be considered to be animals. Apart from a few sedentary species, most Protozoa are motile. Because they have difficulty in retaining water, partly because of their small size, most live in aquatic (or at least moist) environments. Although the majority of protozoans are free living, many species are mutualists, commensals, or true parasites. Some are highly pathogenic to their plant or vertebrate hosts and hence are relevant to veterinary and human medicine and agriculture (Mehlhorn 2002).

GENERAL MORPHOLOGY OF PARASITIC PROTOZOA

The classification of the Protozoa remains in flux, as new data continue to be obtained (see Classification and introduction to the parasitic protozoa and Mehlhorn 2002). Some of the attributes of the protozoans are, however, beyond dispute. For example, they are all organized according to the basic pattern of the eukaryotic cell (Figure 1), the same type being found in all metazoan cells.

Eukaryotic cells consist of a membrane-bound cytoplasm containing one or more nuclei and various organelles that are also often membrane bound, their compartments and membranes acting as sites where reaction processes can occur (Alberts et al. 2002).

Cell membrane

The parasitic protozoans are surrounded by a membrane 4–10 nm thick (the unit membrane or plasmalemma) (Figures 2 and 3). In living cells this membrane always forms a closed sac or vesicle.

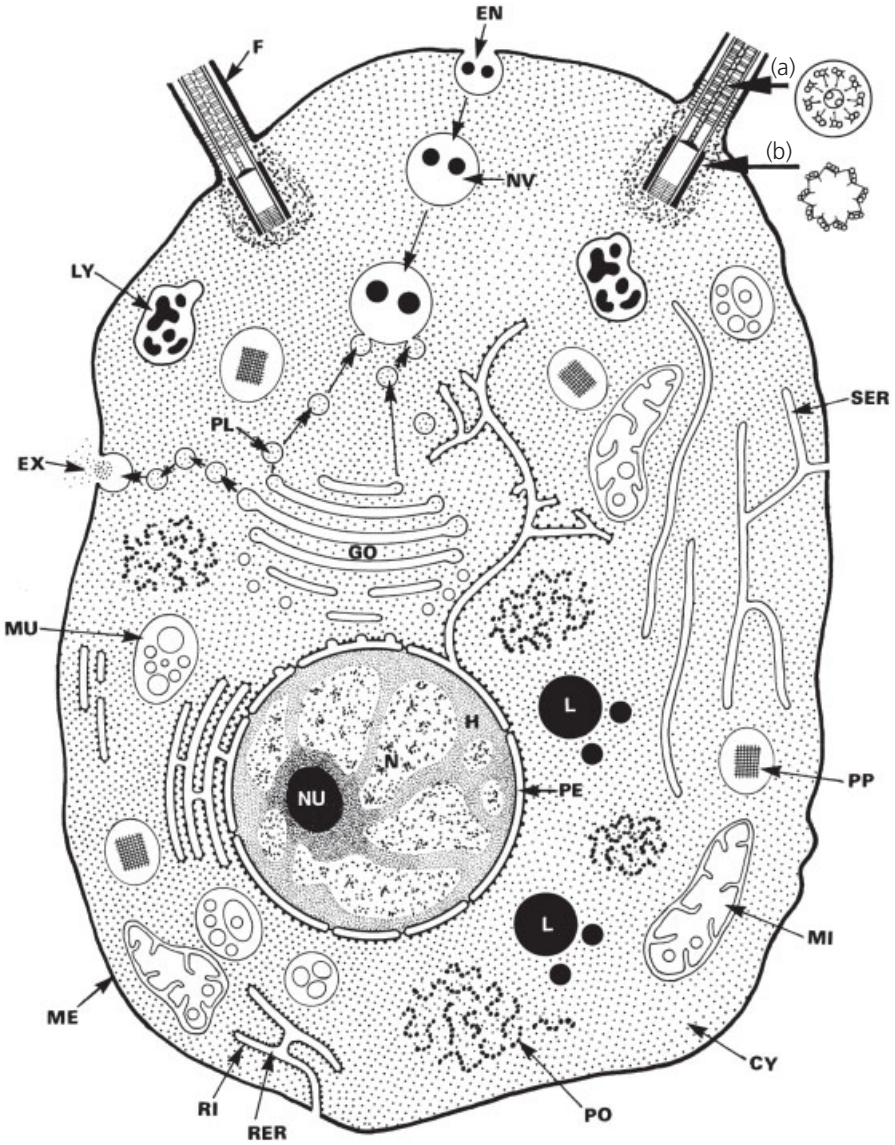

Figure 1 *Fine structure of a typical eukaryotic cell,* **(a)** *cross-section of the free flagellum:* **(b)** *cross-section of the basal body. B, basal body; CT, cytoplasm; EN, endocytosis; EX, exocytosis; F, flagellum; GO, Golgi apparatus; H, heterochromatin; L, lipid; LY, secondary lysosome (phagolysosome); ME, cell membrane (plus surface coat); MI, mitochondrion; MU, multivesicular body; N, nucleus; NU, nucleolus; NV, food vacuole (endocytotic vacuole); PE, perinuclear space; PL, primary lysosomes; P0, polyribosomes (chains); PP, peroxisome with protein crystal; RER, rough endoplasmic reticulum; RI, ribosome; SER, smooth endoplasmatic reticulum.*

The membrane is composed of species-specific amounts of various proteins and a double layer of lipids (Figure 2). It is physiologically and morphologically asymmetric, presenting a 'p face' (directed towards the cytoplasm) and an external 'e face.' High-magnification electron microscopy reveals that it is trilaminar (composed of three layers) (Figure 3). It is semipermeable, i.e. only certain types of molecules may cross it (Gennis 1989).

Several models have been created to explain how this biomembrane functions. The most widely accepted is the fluid mosaic model of Singer and Nicolson (1972) in which it is proposed that the membrane consists of a relatively stable double layer of lipid molecules within which proteins float like icebergs. At least some of the proteins may be structured to form pores or channels (Figure 2). The membranes expand by additive inclusion of vesicles formed inside the cytoplasm and shrink by formation of endocytotic vesicles (Figure 1) (Neupert and Lill 1992).

There are several systems for transporting substances through the cell membrane into the cytoplasm. Passage may occur by permeation (nonmediated transport), a process that is dependent on concentration gradients. Active transport (mediated transport) using motile carriers may also occur. In this system a protein binds

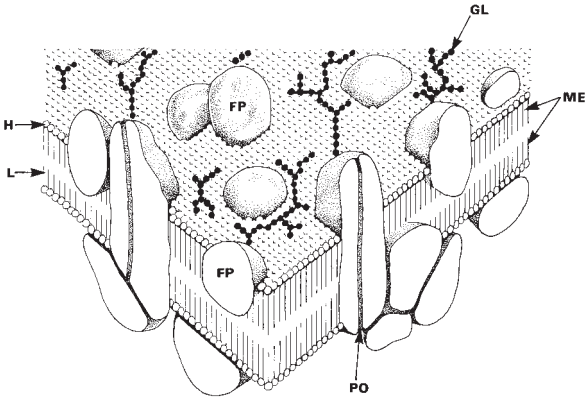

Figure 2 *Cell membrane of a typical eukaryotic cell following the fluid mosaic model of Singer and Nicolson (1972). Proteins (FP) float in a membrane that consists of a double layer of lipid molecules each with a hydrophilic component (H) and two lipophilic layers (L). The proteins, which may form pores (PO), often anchor glycoproteins, and together form the glycocalyx (GL).*

the molecule to be transported and then the complex moves actively from one side of the membrane to the other. Movement depends on changes in the electric charge that are linked with the binding and release of the transported molecule. The fixed pore (Figure 2) is a protein structure that stretches through the membrane. The molecules to be transported pass through the space, or channel, formed between the subunits of the pore. All forms of active transport require energy, which is derived from various metabolic reactions.

In addition to the direct transport of molecules through the cell membrane, other mechanisms exist for internalization of materials by cells. For example, relatively large organic materials may be internalized by the formation of endocytotic vesicles (Figure 2), a process termed pinocytosis for the uptake of liquids and phagocytosis for the uptake of solid particles. Within the vacuoles the material is degraded and then transported into the cytoplasm by mechanisms similar to those used by the cell membrane. Alternatively, it may be released by dissolution of the membrane. Some protozoans have developed special places for the uptake of food, called cytostomes. Many cells contain clathrin-coated pits that are involved in the receptor-mediated endocytosis of macromolecules, but our knowledge of coated pits in Protozoa remains limited (Morgan et al. 2002), although clathrin-dependent endocytosis has been seen in trypanosomes.

The cell membranes of both Protozoa and Metazoa are involved in many other tasks apart from transport functions, for example cell recognition. When cells come into contact with each other, recognition occurs via special receptors in the membranes that perceive chemical signals given off by other cells. Cell membranes also participate in excretion and secretion, these processes occurring by mechanisms similar to those for the intake of materials (e.g. bloodstream trypanosomes excrete trypanopains and oligopeptidases in order to cross the blood–brain barrier; Londsdale-Eccles and Grab 2002). Membrane-bound structures exist that mediate the joining of cells. These are needed for fusion of gametes and similar structures and are also found at places where flagella are attached to the surfaces of protozoa. The undulating membranes and recurrent flagella of trypanosomes and trichomonads are joined to the cell by means of such cell junctions (Figure 4; see also Figure 29a). Cell junctions also play a role in attachment of many parasites to the surfaces of host cells. For example, trypanosomes use junctions for attachment to the vector's intestine.

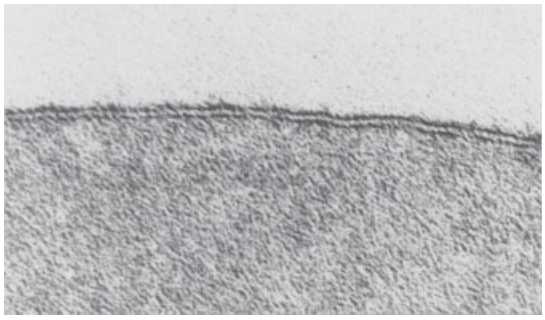

Figure 3 *Transmission electron micrograph of a section through the membrane of an erythrocyte showing the three layers of the membrane (× 100 000).*

Pellicle and cytostomes

Many protozoans have more than one limiting membrane for at least some of their developmental stages (Table 2). In some groups the main cell membrane is underlined by one or more 'inner' membranes that are often derived from the endoplasmic reticulum (Table 2, Figure 5).

Like the outer membranes, these inner membranes are species specific and possess distinct inner and outer surfaces. The characteristics of the inner membranes have been revealed by the methods of freeze fracture and negative staining (Figure 6). The single outer membrane and the membranous complexes often have subpellicular microtubules (c. 25 nm in diameter) beneath them.

These shape-stabilizing cell boundary complexes are called pellicles (Figures 4 and 5). The motile stages of trypanosomes and *Leishmania* species form a pellicle that consists of one membrane plus underlying microtubules (Figure 7), whereas the motile stages of coccidians (sporozoites, merozoites, ookinetes, kinetes) have a pellicle consisting of three membranes plus underlying microtubules (Figure 6).

In ciliates the pellicle is composed of an outer membrane, a system of alveolar sacs, longitudinal micro-

tubules, and kinetodesmal fibres. This complex pellicle produces a stable base to hold rows of cilia (see Figure 18).

In the free-living euglenids the plasmalemma is reinforced by longitudinal microtubules and by a dense underlying epiplasm. The number of subpellicular microtubules is often stable within a species and may thus be used for species definition. For example, the merozoites of the tissue cyst-forming Coccidia (e.g. *Sarcocystis*, *Toxoplasma*, *Besnoitia*, *Frenkelia*) always have 22 microtubules and various *Eimeria* species have 24, 26, 28, 30, or 32 microtubules, respectively. In some parasites, such as the trypanosomatids, the number of subpellicular microtubules varies with the size of the individual parasite form, i.e. a long slender form with a small diameter has fewer microtubules than a form of the same species with a larger diameter (Figure 7).

The subpellicular microtubules may run from one pole to the other, as they do in gregarines and trypanosomes, or they may be restricted to limited portions of the pellicle. In ciliates, for example, they are restricted to the front half of the cell and in the coccidian motile stages they are localized to the front two thirds of the cell (Figure 8).

In the motile stages of the Coccidia the microtubules are anchored to an anterior polar ring. At the attachment point there is an interruption of the two inner membranes (Figure 9). If two or more polar rings are present (species specific), it is the outer one that is connected to the microtubules. The subpellicular microtubules are usually kept in contact with the inner surface of the pellicular membrane by means of side arms. The exact role of the microtubules in movement has not yet been identified.

The membrane of the eukaryotic cell can take up material by various methods including permeation, active transport and endocytosis. Endocytosis (see Figure 1) may occur at any point on the cell membrane or may occur only at predisposed places. For example, in *Giardia* trophozoites, endocytosis occurs only in the dorsal region, the region opposite the ventral sucker; in trypanosomes, endocytosis occurs in the flagellar pocket (Morgan et al. 2002) and in sporozoans it is found at small cytostomes called micropores (Figure 10) (Mehlhorn 2002).

Large endocytic elements (cytostomes or 'cell mouths') are characteristic of many ciliates (see Figure 31e) (Hausmann et al. 2003).

Cytostomes are reinforced by various structures (Figure 10), for instance by bundles of microtubules in trypanosomes and ciliates. After the phagosomes enter the cytoplasm the contents are digested and resorption of the necessary molecules occurs. The residue may be voided to the outside or stored as an inclusion. The process of excretion, called exocytosis, may occur anywhere on the surface or, as in ciliates, at a specialized place called the 'cell anus' or cytopyge. Exocytosis is a process similar to endocytosis but in reverse.

Cyst wall

Many parasitic protozoans (Table 2) are capable of undergoing encystation, which involves formation of a cyst wall either outside or inside the cell membrane. This cyst wall may be single layered or multilayered.

Walls formed outside the plasmalemma are produced by exocytosis of materials. Cyst walls have two main

tasks: to protect the organism against unfavorable environmental conditions when passing from one host to another and to create spaces for reorganization and nuclear division. Cyst walls may also aid the parasite in transmission from one host to another by facilitating attachment to host-cell surfaces.

The cyst wall has one layer in cysts of *Entamoeba histolytica*, *Giardia* species, and some ciliates, such as the fish parasite *Ichthyophthirius multifiliis* and the human ciliate parasite *Balantidium coli*. There are usually two types of cysts in the sages of Coccidia in feces: the oocysts and the sporocysts. The oocyst wall is usually double-layered, but in a few species it may have four layers. It is formed by two types of cyst wall-forming bodies. The sporocyst wall usually has only a single layer (Figure 11).

The chemical composition of cyst walls varies according to the species, although proteins are usually the basic component. The cyst walls of *E. histolytica* and *G. lamblia* contain proteins which are keratin-like or elastin-like albuminoids composed of lysine, histidine, arginine, tyrosine, glutamic acid, and glycine. The double-layered oocyst wall of the sporozoans is periodic acid–Schiff (PAS) positive. The outermost layer of these oocysts consists mainly of fatty alcohols (e.g. hexacosanol), some phospholipids, and fatty acids. It has no carbohydrates or proteins. The inner layer is composed of glycoproteins and contains most of the carbohydrates found in the oocyst wall. These carbohydrates are composed of mannose, galactose, glucose, and hexosamine. The oocyst wall is highly resistant to the passage of potassium dichromate, sodium hypochloride, sulfuric acid, and sodium hydroxide and these chemicals are therefore used in storage and cleaning of oocysts. The oocyst wall is permeable to oxygen, carbon dioxide, ammonia, methylbromide, carbon disulfide, and various organic solvents. It is highly susceptible to mechanical pressure and therefore may easily be ruptured by shearing forces. Thus mechanical rupture of oocysts in the gizzard of the avian host is likely to be the normal method of excystation of avian coccidians. The micropyle (a preformed opening in some species) is probably used as rupture point to facilitate the escape of sporocysts. The sporocysts in the oocyst are bound by a double-layered wall, the outer layer of which is relatively smooth. The sporocysts of eimerians have an opening for exit of the sporozoites. This is closed by the Stieda body, which can be dissolved by trypsin. The sporocysts of *Isospora* and the tissue cyst-forming Coccidia (*Sarcocystis*, *Toxoplasma*) have sutures on which the excystation fluids act causing collapse of the sporocyst wall (Figure 11g).

The cyst walls of Myxozoa and Microspora are at least double-walled in most species (Figure 12) and the layers can be resolved by electron microscopy. In Myxozoa the wall consists of valves that open at preformed sites to release the infectious sporoplasm.

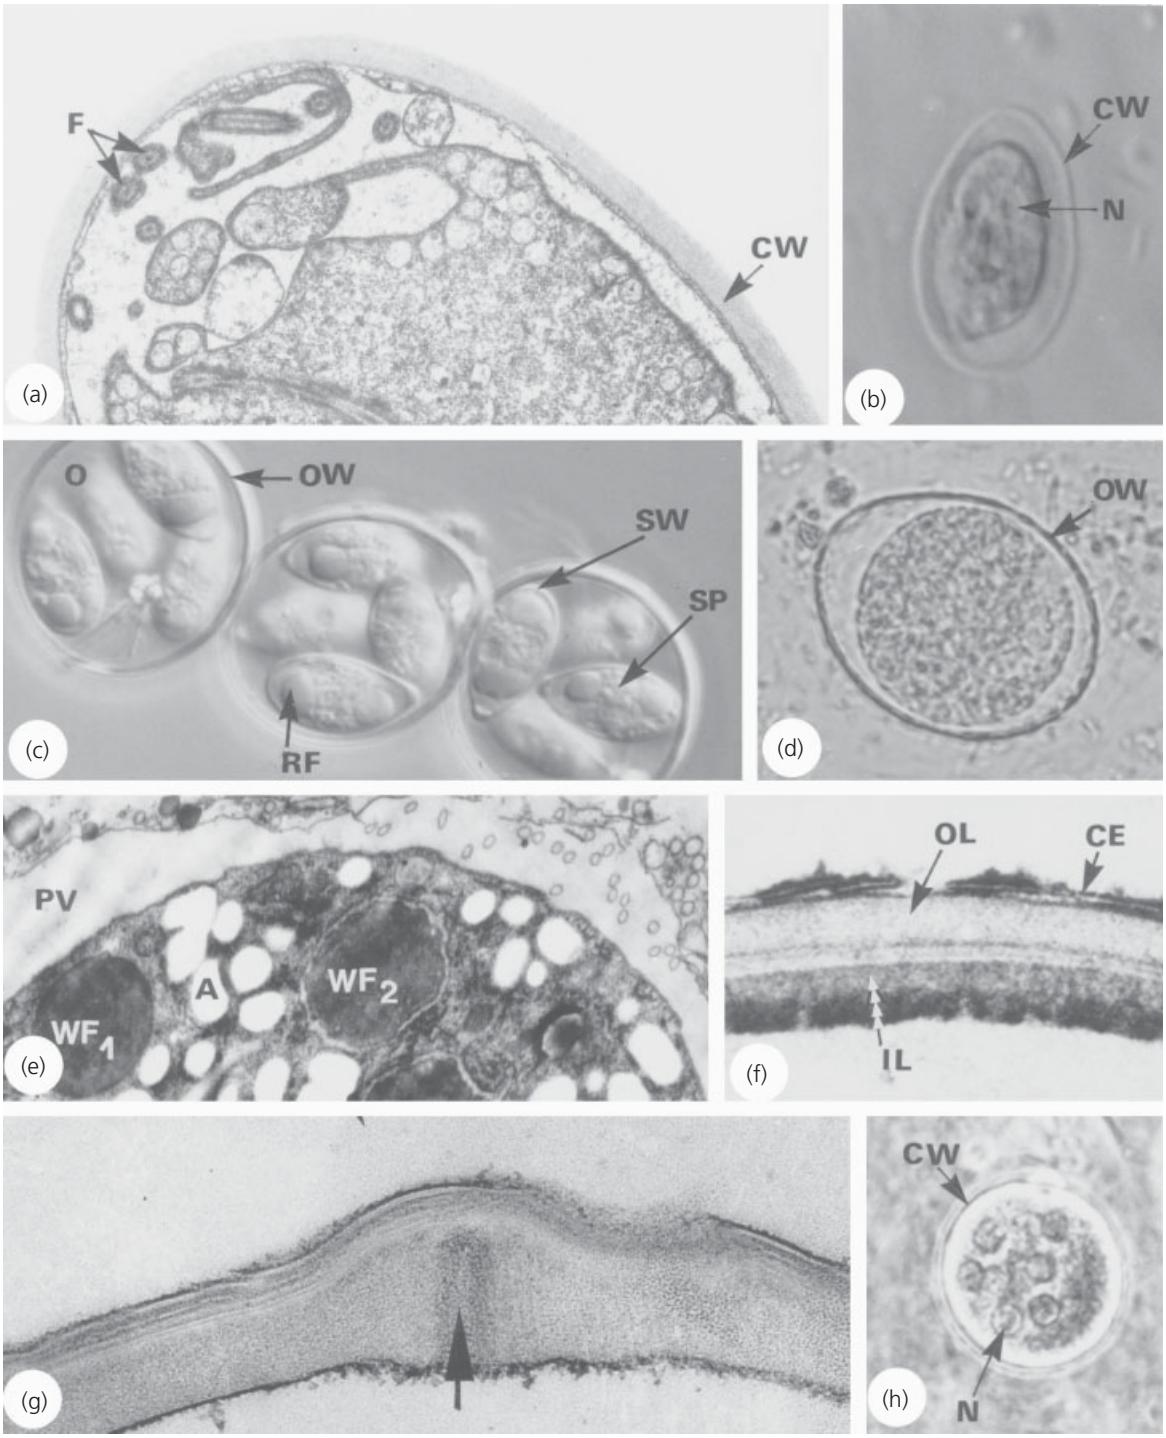

Figure 11 *Light (b, c, d, h) and electron micrographs (a, e, f, g) of cysts and cyst walls. The Microspora have developed a hollow tube that is protruded from the surface of the wall. It penetrates into a host cell and the infectious sporoplasm is passed through it. The exospore layer in Microspora is proteinaceous and is 15–100 nm thick, depending on the species. The endospore layer is chitinous and

c. 150–200 nm thick. The spores are gram-positive (i.e. stain reddish purple with the Gram stain), a fact that is of diagnostic value. They are also stained light blue by Giemsa.

Surface coat

The plasma membrane of eukaryotic cells is strikingly asymmetric (Figure 2). The outer and inner layers are clearly delineated and the polypeptides on each surface (Figures 13 and 14) are distinct. Glycolipids and glycoproteins are present only on the external surface. The peripheral layer is rich in carbohydrate and is called the glycocalyx or surface coat. Molecules of glycosylphosphatidylinositol (GPI) serve as parasite-specific anchors for numerous surface proteins. The thickness of this layer varies with the species and with the developmental stage of the organism. Not only is the surface coat composed of glycoproteins and glycolipids, but various glycoproteins and proteoglycans (acid mucopolysaccharides) may also be adsorbed to it (Figure 13).

The surface coat may be a rather delicate coating, a mass of delicate filaments or a thick mat. Whatever its structure, it has several functions in the life of the organism: (1) it acts as a mechanical or chemical barrier; (2) it plays a role in recognition and adhesion to other cells; (3) it contains enzymes that act on substances in the environment; and (4) it contains molecules that can act as antigens and thus plays an important role in immunological processes.

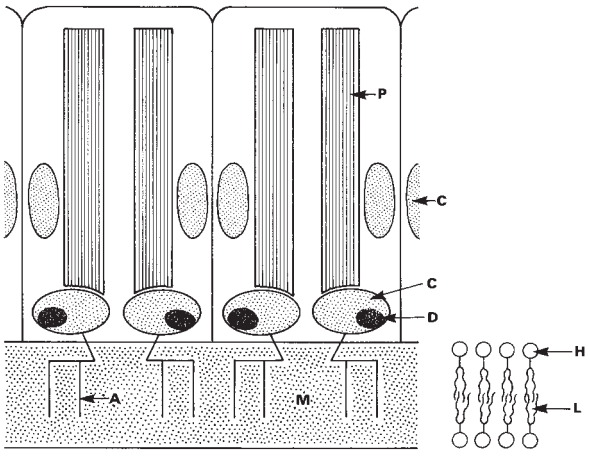

Figure 13 *Arrangement of the components of the surface coat along the surface of a trypanosome. A, anchor of a variant surface glycoprotein molecule; C, carbohydrate; D, cross-reacting determinant; H, hydrophilic component of the VSG molecule; L, lipophilic component; M, membrane consisting of two layers of lipid molecules; P, protein.*

Cross-section through a trypomastigote stage showing the discharge of the surface coat (arrow). AX, axoneme; F, flagellum; PR, paraxial rod; ST, subpellicular microtubule (×25 000).*

The surface coat may change its composition as the parasite develops from stage to stage. In addition, many parasitic Protozoa, in particular the trypanosomes, have developed sophisticated methods of antigenic variation. This may be achieved by selective activation of different genes at different times. Organisms of the *Trypanosoma brucei* group have up to 1 000 genes that may become activated during the production of variant surface glycoproteins (VSGs). This selective activation results in changes in the variable antigen types (VATs) displayed and hinders the host defense against these blood-inhabiting flagellates. *Plasmodium* may also display variant antigen types, but there are fewer variants than those displayed by trypanosomes. Such different surface antigens (SAGs) are found in many of the coccidians, too (Lyons et al. 2002). The action of these genes results in antigenic variation and the production of immunologically different strains of protozoans; this explains why most antiprotozoal vaccines provide only limited protection, restricted to certain localities. The development of potent vaccines against protozoan parasites depends on the discovery of species-specific antigens with invariant epitopes that are accessible to the immune system during the parasite's life. In addition, they must be essential to the parasite's survival, possibly playing an important role in cell recognition, adhesion, immune evasion, metabolism, or cell invasion.

Cytoplasm

The cytoplasm in protozoa is generally divided into two zones: the peripheral, electron-lucent ectoplasm (hyaloplasm) and the denser central endoplasm. The endoplasm contains the cell organelles and the nucleus. This differentiation is particularly prominent in the amoebae and in the gregarines (Figures 15 and 16) but is not apparent in all species.

In some species, endoplasm and ectoplasm cannot even be distinguished by electron microscopy. Microgametes of most sporozoans, apart from those of the piroplasms, have a very reduced cytoplasm. They are comprised mainly of flagella, a mitochondrion, and a nucleus (Figure 17) (Mehlhorn 2002; Ferguson 2002).

The cytoplasm of most cells has a high viscosity and stability and a prominent cytoskeleton. Contractile elements of this cytoskeleton are responsible for the cytoplasmic flow and these include actin filaments with a diameter of c. 6 nm. These filaments are composed of a double chain of globular bodies. Cytoskeletons may also contain 10 nm filaments or intermediate filaments which,

to date, have been found only in the cells of higher vertebrates. The various types of filaments are organized into the microtubules of the cytoskeleton. The tubules have an outer diameter of 25 nm and an inner diameter of 15 nm. They are composed of protofilaments that are visible in cross-section. The protofilaments consist of α and β tubulin elements in a helical arrangement. The microtubules are polymerized at particular points called microtubule organizing centers (MTOCs). These centers exist at centromeres, centrioles, and at certain places in membranes. They also occur as constituents of flagella and cilia (see Figures 28 and 29).

The processes that bring about motility of the cytoplasm are well documented for metazoan cells, but for protozoans they are still poorly understood (Figure 17). In all cases, it is probably the aggregation of actin with myosin and tropomyosin to form an actomyosin complex that leads to movement, as proposed in the early sliding filament model of Huxley and Hanson (1954). This ATP-dependent system may produce relatively rapid movements, as occur in amoeba (20 μm s^{-1}) and in the sporozoites and merozoites of sporozoans. In addition to the cytoskeletal system, most parasitic protozoans have developed unique skeletal elements composed of combinations of the usual cytoskeleton elements. These structures include the following:

- subpellicular microtubules of trypanosomes and the motile stages of the Coccidia (see Figures 4 and 5)
- kinetodesmal fibrils of ciliates (Figure 18a)
- bundles of cytoplasmic microtubules in gamonts of piroplasms (Figure 18b)
- combined microtubules and filaments observed in the ventral disc of the diplomonadids (Figure 18c)
- crystalloid protein densifications that occur below the membrane of giardial trophozoites, at the apex of eimerian microgametes (Figure 18d) and also in the gamonts of piroplasms (Figure 18b)
- axostyles and pelta, occurring prominently in the trichomonads and consisting of one or more parallel rows of microtubules (Figure 19)
- costa and parabasal filaments, the filamentous, sometimes striated elements (Figure 19) that line the

and *Toxoplasma* (see Figures 8 and 9a), but which are always absent from the hemosporidians (e.g. genera *Plasmodium*, *Theileria*, *Babesia*).

The conoid (Figure 9a) is a hollow truncated cone composed of spiralling microtubules 25 nm in diameter. Two accessory structures, the conoidal or preconoidal rings, form an integral part of the conoid and they are connected with each other by a canopy-like membrane. During cell penetration the conoid protrudes through the anterior polar ring system. The conoid is apparently involved in penetration of host cells.

CYTOPLASMIC INCLUSIONS

The endoplasm contains a variety of organelles and other structures within which metabolic processes occur.

Nucleus

Protozoa possess at least one well-developed nucleus that is usually spherical to ovoid (Figure 20) and enclosed by a double-layered membrane containing pores (Figures 1 and 21). The pores are c. 50–70 nm in diameter with a central opening made up of eight subunits.

When viewed by light microscopy, the nuclei may appear vesicular or compact. The karyoplasm is composed of structural and enigmatic proteins: the chromatin (DNA) which may be organized into chromosomes; and the nucleolus. No membranes exist within the nucleus. There is usually only one nucleolus but in some species, and in certain developmental stages of other species, there may be several. The nucleolus is the site of synthesis of the large RNAs (28S, 18S, and 5.8S) and of the precursors of the ribosomes. It has two zones; one is composed of filaments 5–8 nm wide and the other is composed of granules 15 nm wide. The granular zone is situated at the periphery of the nucleolus. During nuclear division the nucleoli arc often dissolved and the chromosomes may condense and become visible (e.g. in ciliates) or they may remain stretched out and invisible (e.g. in the eimerians and the hemosporidians). The nuclear membranes are retained in the protozoans during division. Separation of the chromosomes is carried out by a spindle apparatus, the appearance, arrangement, and placement of which is species specific. The apparatus always consists of microtubules and filaments.

In ciliates, two morphologically distinct nuclei occur: a generative micronucleus and a somatic macronucleus (see Figure 31e). In other parasitic species, and in some specific stages such as the meronts, sporonts, and gamonts of the coccidia and hemosporidia, there may be many nuclei, all of which may have a similar appearance. Morphologically similar nuclei may have similar functions or they may have different functions, as in the Myxosporea. During binary division the karyoplasm is usually completely distributed between the two daughter nuclei. In some cases, e.g. during the formation of microgametes in some coccidians, only one functional nucleus is produced and a part of the nucleus is left behind (see Figure 32c, e).

Mitochondria and related structures

Mitochondria contain the enzymes for oxidative phosphorylation and the tricarboxylic acid cycle, and are bounded by two membranes. Most parasitic Protozoa have one of three basic types of mitochondria, distinguished by characteristic infoldings of the inner

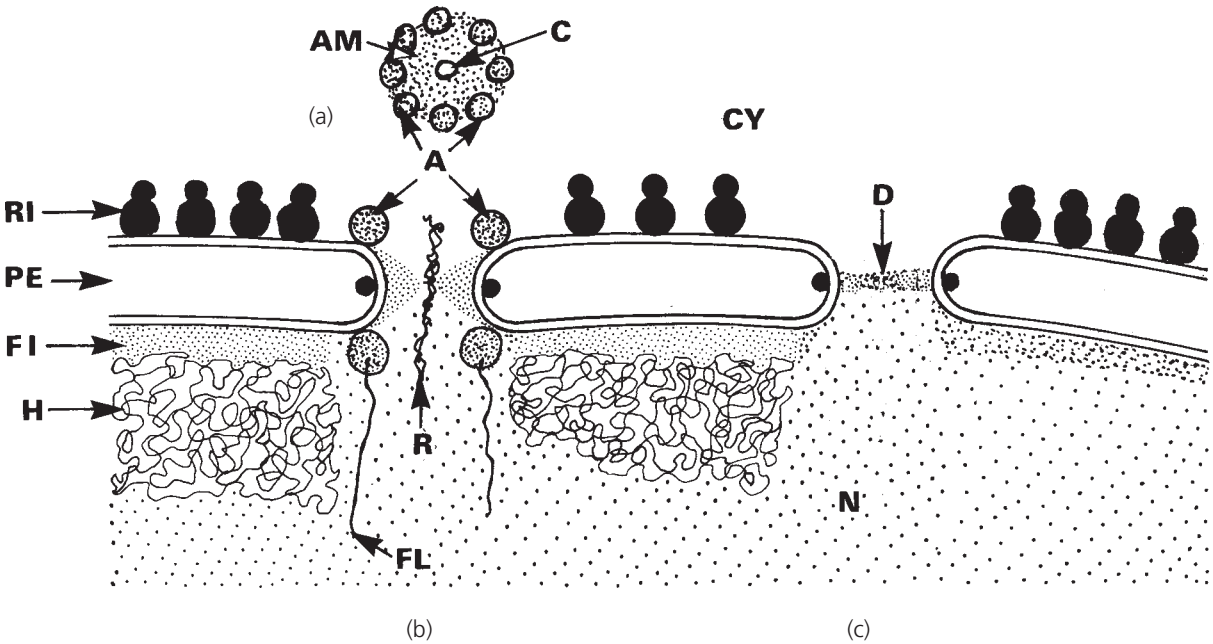

Figure 21 *Nuclear pores (diameter c. 80 nm):* **(a)** *Surface view showing the eight outer peripheral annuli.* **(b)** *Longitudinal section of an active pore.* **(c)** *Longitudinal section of an inactive pore. membrane, which may be tubular, sack-like, or cristae-like (Figure 22).

Mitochondria reproduce by division and are therefore said to be semiautonomous organelles. This form of reproduction is possible because mitochondria have their own DNA. In most mitochondria this DNA is composed of two circular strands arranged in a supercoil. Some species have a single, large mitochondrion that contains more DNA, e.g. species of *Trypanosoma* and *Leishmania*. These organisms have 5 percent of their DNA in a single structure called the kinetoplast (Figures 4 and 7.22a) which is located close to the basal body of the flagellum. Kinetoplastid flagellates have no infoldings in this region of the mitochondria, providing space for the thousands of minicircles (0.3–0.8 μm in length) and the few maxicircles (9–11 μm in length) that make up their mitochondrial DNA; this region stains with Giemsa solution and is visible as a deep purple dot. Only the DNA of the maxicircles seems to be transcribed. During cell division the kinetoplast is always reproduced before nuclear division occurs. Trichomonads, some amoeba (e.g. *Entamoeba histolytica*), and Microspora have no mitochondria, but some amoeba contain symbiotic bacteria that may function as mitochondria. The trichomonads, which are anaerobic, have microbodies called hydrogenosomes. These spherical organelles have two closely attached membranes surrounding a granular matrix (Figure 19). The enzyme system of these bodies differs from that of mitochondria, as they metabolize pyruvate from glycolysis into acetate, carbon dioxide, and hydrogen. In ciliates, hydrogenosomes with more easily visible double membranes are present, as well as mitochondria.

The motile stages of sporozoans (i.e. merozoites and sporozoites, Figures 23 and 7.24a) have a Golgi-adjunct body (also called a double-walled organelle) close to the nucleus (Scholtyseck and Mehlhorn 1972).

In several species and genera (e.g. *T. gondii*, *Sarcocystis*, and *Plasmodium*) this organelle contains genes of the photosystem II and resembles a plastid, or a remnant of one, in terms of shape and activity (Hackstein et al. 1995). This body is now called the apicoplast and has been found to contain a third genome (in addition to that of the nucleus and mitochondria).

Endoplasmic reticulum, ribosomes, and golgi apparatus

The endoplasmic reticulum (ER) is a large system of tubes and sacs that runs throughout the cell. It connects the nuclear space with the cell interior and with the cell surface (Figures 1 and 25). There are two types of ER: rough endoplasmic reticulum (rER) and smooth endoplasmic reticulum (sER).

The rER is characterized by the presence of ribosomes (Figures 1 and 25) along its outer surface, whereas these are lacking in the sER. The rER and the sER may be interconnected.

The ribosomes consist of RNA and protein. The ribosomal RNA represents about four-fifths of the total cellular RNA. There are several types of ribosomes, depending on the nature of their subunits (Table 1; Figure 20); these subunits can be released by appropriate treatment of the ribosomal proteins. Several ribosomes often align in a chain to form polyribosomes, or polysomes (Figures 1 and 25), where they are collectively active in protein synthesis. Ribosomes occur along the surface of the rER, either singly or as polysomes. They also occur in the cytoplasm and inside the mitochondria. In Protozoa, ribosomes have a diameter of c. 30 nm and are composed of two subunits with sedimentation characteristics of 60S and 40S. The intact

ribosome is of the 80S type. Mitochondrial ribosomes are of the 70S type or, in ciliates, 80S. The mitochondrial ribosomes are similar to those of prokaryotes (Bielka 1982) (see Table 1).

The Golgi apparatus is a flat sac with swollen regions (Figures 1 and 26), from which vesicles are formed (Farquhar and Palade 1981). Several Golgi apparatuses together form dictyosomes. These organelles are always situated close to the rER and the two organelles act together as functional units in the production and transport of membrane and in the formation and transport of all types of macromolecular proteins and lipids (Gal and Raikhel 1993). The Golgi apparatus is never covered by ribosomes. Although many parasitic protozoans have prominent dictyosomes, certain developmental stages of protozoans have only a single Golgi apparatus which is difficult to detect in electron micrographs. The principal function of the Golgi apparatus is the transport of secretions and excretions formed on the rER. These reach the Golgi apparatus at its cis side and are transported within vacuoles that are cut off at its periphery (the trans region) (Figure 26). Endocytotic vesicles such as food vacuoles also come into contact with the Golgi apparatus and the rER system at points where they fuse

with enzyme-containing vacuoles produced by the Golgi apparatus; this is how digestive enzymes and other products enter the endocytotic vacuoles.

Lysosomes

Lysosomes are vesicles measuring 0.2–0.5 μm, bound by a single membrane. They are derived from the sER and are formed and released from the secretion side of the Golgi apparatus (the trans side). They contain enzymes such as phosphatases, proteinases, lipases, and nucleases, and have an internal pH of 4–5. When first released they are called primary lysosomes. After fusion with the endocytotic vesicles their enzymes become active and the vesicle is then called a secondary lysosome. In these secondary lysosomes, or phagolysosomes, the ingested food is dispersed (Figures 1 and 26). Another type of secondary lysosome is the autolysosome, which is involved in the disintegration of cellular waste material, thus providing the function of disposal of debris. In *Leishmania* species so-called megasomes (reaching the size of the nucleus) may occur as special type of lysomal vacuole.

Microbodies

Microbodies are ubiquitous in eukaryotic cells. Several types of microbodies have been described (de Souza 2002):

- Hydrogenosomes (Benchimol 1999) are mostly spherical and occur in trichomonads. They reach a diameter of about 0.5–1 μm, are bound by two closely attached membranes, and reproduce by binary fission. However, they do not contain nucleic acid. Thus their proteins are synthesized in free ribosomes and post-translationally inserted into the organelle. As shown by biochemical methods, hydrogenosomes produce ATP and the molecular hydrogen that gives them their name.
- Peroxisomes (called glycosomes in trypanosomatids). These spherical, dense-appearing organelles are membrane-bound, randomly distributed throughout the cell, and reach a size of 0.7 μm diameter. Their name comes from the fact that they usually contain enzymes which use molecular oxygen to remove hydrogen atoms from organic substrate via an oxidative reaction, thus producing hydrogen peroxide

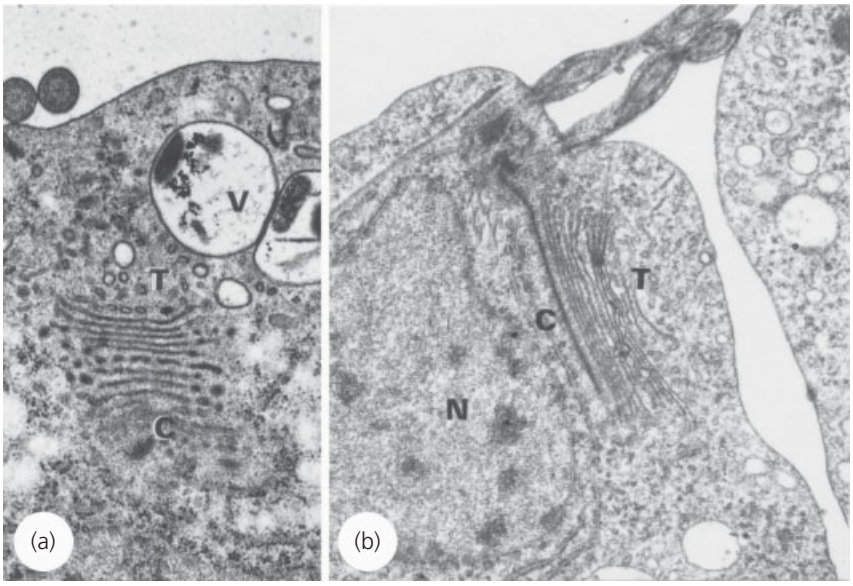

Figure 26 *Transmission electron micrograph of the Golgi apparatus in* Trichomonas vaginalis. *Note the active forms* **(a)** *and the inactive ones* **(b)** *(×20 000). C,* cis *side of Golgi; N, nucleus; T,* trans *side of Golgi; V, food vacuole.*

(H_2O_2). Furthermore, the peroxisomes contain catalase, which utilizes the H_2O_2 to oxidize a variety of other substrates by the so-called peroxidative reaction. In the case of the peroxisomes of trypanosomatids it has been clearly shown that they contain glycolytic enzymes being involved in the conversion of glucose to 3-phosphoglycerate (Opperdoes 1987). These bodies (originally named glycosomes) do not possess a genome and are thus encoded by nuclear genes as are the other peroxisomes. Reproduction occurs via binary fission.

- Acidocalcisomes (formerly designated in light microscopy as 'volutin granules') occur in large numbers in trypanosomes as spherical organelles of about 200 nm in diameter in all regions of the cell. They are limited by a 6-nm thick membrane and are involved in the storage and exchange of calcium, magnesium, and zinc ions (Docampo and Moreno 2001).
- Glyoxisomes of many protozoans process lipids for energy production. The reservosomes of *Trypanosoma cruzi* are spherical, reaching diameters of 0.7 μm and include all macromolecules ingested during the endocytic processes in the flagellar pocket. Also cruzipain, the major cysteine proteinase in the cell, is accumulated with reservosomes.

Rhoptries, micronemes, and dense bodies

The osmiophilic rhoptries, micronemes, and dense bodies are characteristic of the motile stages of sporozoans. They are usually located in the area between the nucleus and the apical pole. Rhoptries vary considerably in number (2–20) and in shape, appearing club-shaped (*Eimeria*), teardrop shaped (*Plasmodium*), or elongated (*Sarcocystis*, *Toxoplasma*). The anterior neck portions of rhoptries are narrow and duct-like and are found at the extreme tip of the cell running through the conoid if one is present (Figures 8 and 24). Rhoptries release enzymes (Rhop 1–20) during the penetration process, after which they appear partly empty with a sponge-like interior. Micronemes are small rod-like structures 50–90 × 300–600 nm with rounded ends. These structures usually occupy the anterior regions of the motile stages of the sporozoans and are often arranged in bundles (Figures 24 and 27). The function of micronemes is not completely understood, although it is known that they contain at least seven proteins, which are used during adhesion of the parasite to the host cell as is the case in the so-called circumsporozoite protein (CSP) of *Plasmodium* species. Dense bodies (0.2 μm) are found at the anterior part of penetrating coccidian stages. At least six different proteins (GRA 1–6) are released during penetration into the parasitophorous vacuole (as defense against the digestive enzymes of the host cell?). They disappear during the reproductive process in meronts, macrogamonts, and microgamonts.

Wall-forming bodies

Parasites that produce walled cysts, such as amoebae, *Giardia*, coccidians, *Balantidium*, Myxozoa, and Microspora, develop wall-forming bodies of various types (see Figures 11e and 12). In amoebae, diplomonadids, Microspora, and Myxozoa, the contents of the wall-forming bodies fuse outside the cell after being excreted by exocytosis. This fused material forms an external cyst wall (see Figure 12). In macrogametes of coccidia the wall-forming bodies fuse in the region immediately below the cell membrane, thus producing an internal cyst wall (see Figure 11).

One or two different types of wall-forming body may occur in coccidia of the various genera. For example, in *Eimeria* and *Isospora* the macrogametes have two types of wall-forming bodies: (1) electron-dense bodies that give rise to the outer layer of the oocyst wall; and (2) sponge-like bodies that fuse to produce the inner layer of the oocyst wall. The entire oocyst wall is produced

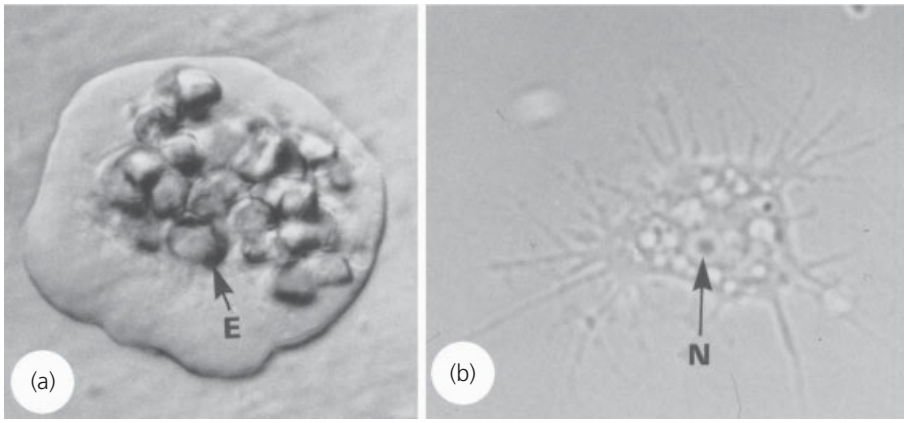

Figure 27 *Light micrographs showing amoebae with lobopodia* **(a)** *and filopodia (h):* **(a)** Entamoeba histolytica*, magna form. E, erythrocyte (×2 000).* **(b)** Acanthamoeba castellanii. *N, nucleus (×1 200).*

inside the cell membrane (see Figure 11e). The oocysts of *Sarcocystis* and the sporocysts of all coccidians are bound by a smooth wall that is formed by fusion of a single type of electron-dense wall-forming body (see Figure 11g). The cyst walls of all stages of Coccidia provide good protection against adverse environmental conditions. Whether they are single or double walled, the oocysts and sporocysts of all *Eimeria* have openings, whereas the sporocysts of *Isospora* and of the tissue cyst-forming coccidia have sutures in their walls (Figure 12d).

Vacuoles and storage elements

All parasitic protozoa have various types of vacuoles, the largest of which are the food vacuoles (see Figure 1); these disintegrate during digestion. Vacuoles that serve as storage elements contain crystalloid proteins (Figure 24a), lipids, or carbohydrates (Figure 24c). Lipid-containing vacuoles appear slightly grey in electron micrographs and are present mainly in resting stages such as cysts. Large amounts of protein are found in the refractile bodies of sporozoan sporozoites (Figure 24a) and in *Plasmodium* ookinetes. Carbohydrates are generally stored in the form of granules of glycogen or amylopectin (Figures 24a and 25). Amylopectin-containing granules appear as brilliant white areas in electron micrographs of gregarines, coccidians, and some endoparasitic ciliates. These granules are scattered throughout the cytoplasm of sporozoans of all developmental stages except microgametes, and are particularly numerous in the cytoplasm of macrogametes and oocysts (see Figure 11e). Glycogen (see Figure 14a) is present as small randomly distributed granules in the cytoplasm of *Tritrichomonas foetus* and as a large mass in the cytoplasm near the nucleus in *Entamoeba* or *Iodamoeba* cysts.

Locomotor systems

All protozoa are motile in at least one stage of their life cycle. The different species have developed distinct locomotor systems during their evolution.

Some protozoans use pseudopodia as locomotory organs. These structures, which may occur as thick lobopodia or as fine filopodia (Figure 27), are produced by the cytoplasmic movement mediated by the activity of the calcium-regulated actomyosin complexes. The contraction of filaments of actomyosin causes pressure on the cytoplasm at the posterior pole and this initiates a forward flow of cytoplasm at the apical pole. At the apical pole the amoeboid movement is enhanced by a transformation of the local cytoplasm from a stable gel form to a more liquid sol form (see Figure 16). Pseudopodia are most prominent in the various types of amoeba but may also be found in motile metazoan cells such as leucocytes.

Many protozoans use flagella or cilia as locomotor organs (Hausmann et al. 2003). These structures are constructed according to a common plan. Flagella are longer and generally less numerous than cilia, but their basic structures are similar (Figures 1, 28, and 29).

Both types of organelles are c. 0.2–0.4 μm in diameter and both possess an axoneme (an arrangement of nine pairs of outer microtubules and a single pair of central microtubules) which is anchored to a basal body (kinetosome) that resides inside the cortical cytoplasm of the cell (Figures 1 and 29d). The basal bodies are similar to centrioles in having nine sets of three microtubules arranged in a ring-like pattern. The basal bodies may be connected to filamentous elements such as the kinetodesmal filaments of cilia. Several species of Protozoa have a rod-like structure consisting of a network of protein filaments inside the flagellum (Figures 4, 7, and 29a). These rods lie beside the axoneme, probably adding to the thickness and stability of the flagellum. This enhancement may be particularly important for protozoans living in viscous media such as blood or intestinal fluids. Although flagella and cilia are constructed according to a general blueprint, in different protozoans the paired outer microtubules in the flagella and cilia may differ in shape (Figure 28). The A tubule, which is furnished with two dynein arms, typically possesses 13 protofilaments, whereas the B tubule has only nine protofilaments and shares three to four of the protofilaments of the A tubule. The dynein arms act as enzymes for breaking down ATP and are proposed to represent the motor system in the 'gliding filament' theory. This theory postulates that the movement of flagella and cilia is initiated by the gliding of microtubules along each other using the dynein arms as linking elements. The central regions of flagella are stabilized by spike-like elements

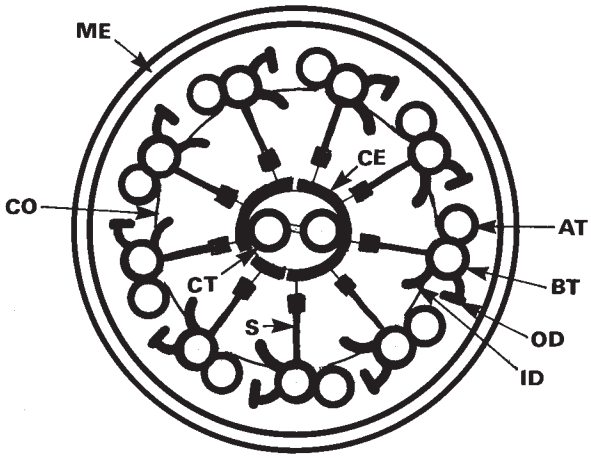

Figure 28 *Diagrammatic representation of a cross-section through a cilium or flagellum. E, extrusomes; MI, mitochondrion; PR, paraxial rod of the flagellum.*

(Figure 28) in addition to the rod mentioned above. In the trichomonads and in the trypomastigote stages of trypanosomes, a flagellum may be connected to the cell surface by desmosomes (Figure 29). The recurrent flagella are attached in this manner and when the attached flagellum pulls the plasmalemma away from the body, the undulating membrane is created. The recurrent flagella never run inside the cytoplasm, but the axonemes of *Giardia* trophozoites run inside the cytoplasm for several micrometers (Figure 18c).

The invasive stages of sporozoans, i.e. the merozoites and sporozoites, have three types of movement: gliding, twisting, and bending. Only the first of these leads to active displacement of the organisms; the other two only change the direction of movement. The gliding form of movement is extremely rare in eukaryotic cells. It is temperature sensitive and cytochalasin B sensitive, the latter property suggesting the participation of actin in the process. The gliding movement may be related to the capping phenomenon in sporozoans. In capping, the organisms aggregate materials on their surfaces and move them towards the posterior pole, from where they release them into the surroundings. A parasite floating in a liquid could move forward using this type of action. The most studied of the capping phenomena is the circumsporozoite reaction of *P. falciparum* sporozoites.

Surface interactions and penetration

Parasites living inside host cells use a variety of means, either active or passive, to enter the host cell. In active processes the parasite's motility mechanisms play a role, whereas in passive processes the host cell internalizes the parasite by a phagocytic mechanism in the same way that food particles are ingested. In all cases, however, entry occurs after an initial recognition step in which some structure on the parasite surface reacts with and binds to some structure on the host-cell surface.

Different types of invasion processes are used by different intracellular pathogens. Some, such as the Microspora, penetrate the host-cell plasmalemma to enter the host-cell cytoplasm, whereas members of *Mycoplasma* and viruses invade by membrane fusion. Many parasites enter their host cells by phagocytosis. After entry by phagocytosis, different parasites follow different paths: the *Leishmania* develop in phagolysosomes; the mycobacteria inhibit fusion of the lysosomes with the phagosomes; and *T. cruzi*, some species of *Leishmania*, and all schizonts of *Theileria* (Piroplasmea) escape from the phagosome into the host-cell cytoplasm.

Some phagocytic processes are quite complex. Some organisms, such as malaria parasites, members of the genera *Eimeria*, *Sarcocystis*, and *Toxoplasma* actively

invade by forming a moving junction between the host membrane and the parasite. After completion of the process, the parasite rests in a parasitophorous vacuole bound by the invaginated host-cell membrane. This parasitophorous vacuole membrane may disintegrate after the parasite has penetrated; for instance, stages of *Babesia* and *Theileria* are located directly in the cytoplasm of their host cells (red blood cells) shortly after invasion is completed (Figure 30a, b).

MODES OF REPRODUCTION

In parasitic protozoans, cell division occurs during both vegetative and sexual development (in which it occurs during the formation of gametes). Cell division may occur in production of gametes of both sexes, as in the gregarines, or only during production of the male gamonts, as in the Coccidia.

Binary fission

The most basic type of multiplication is binary fission (Figure 31). This process produces two daughter cells after duplication of the organelles of the mother cell. The axis of cell division is a characteristic feature of the various groups within the Protozoa, and different types of division can be distinguished: irregular, amoeba-like, longitudinal, oblique, and transverse. In microsporidians (e.g. *Nosema*) binary fissions occur after nuclear divisions in an irregular fashion, the cytoplasm being divided irregularly and different sizes of daughter cells being formed. After freeing, however, the daughter cells all develop a similar shape. In rhizopods such as *Entamoeba* and *Acanthamoeba*, cell division is irregular with respect to the cytoplasm but the constriction always occurs perpendicular to the spindle axis; this is called ameba-like division (Figure 31a). In flagellates such as the diplomonads, trichomonads, and trypanosomatids, and in sporozoans such as the Coccidia, the axis of cell division runs longitudinally and the process is therefore called longitudinal division. In flagellates the polarity of the division axis is determined by the initial axis of duplication of the basal bodies of the flagella (Figure 31b). Unusual binary fissions occur in a few species of sporozoans. For instance, the process by which the merozoites of piroplasms bud from the parent cell, one at a time, could be considered to be an irregular form of binary fission. The processes of endodyogeny in those Coccidia that form tissue cysts is a very peculiar form of longitudinal division (Figure 31d). In this process, two daughter cells are formed within a mother cell, arching over and parallel to the axis of the dividing nucleus. The daughter cells produce the inner two pellicular membranes de novo from the membranes of the endoplasmic reticulum and take over the outer membrane of the mother cell's pellicle. The two inner membranes of the mother cell disintegrate. In trichomonads, the axis (Figure 31c) of cell division is longitudinal at the beginning of the process when the flagellar basal bodies and the nucleus are reduplicated. Later, the divided nuclei move into positions opposite each other and as a result an oblique, or even a transverse, cytoplasmic division occurs.

In opalinid flagellates, which are characterized by oblique rows of 'cilia,' binary fission occurs during the sexual and asexual developmental phases (Figure 31f). The axis of the cytoplasmic division initially runs longitudinally, but soon becomes parallel to the oblique rows of cilia. This is called oblique division. It is intermediate between the longitudinal fission of flagellates and the transverse division of ciliates.

In ciliates such as *Balantidium* and *Ichthyophthirius*, binary fission starts with the duplication of the cytostomal kinetosomes (basal bodies) and is followed by the division of the macronuclei and micronuclei. The axis of cytoplasmic division runs perpendicular to the axis of the nuclear spindles. Cell constriction may occur simultaneously with nuclear division or there may be a time lag. This process is also called oblique division, or, as the division proceeds across the rows of the cilia, it is also described as homothetogenic fission (Figure 31e).

Rosette-like multiplication

If division of the cytoplasm is incomplete or delayed after nuclear division, the pair of newly formed nuclei may divide again before cytoplasmic division occurs. This may result in the simultaneous development of more than two offspring. In some cases the offspring remain attached at their posterior poles for some time, forming a mass that may appear as a rosette in stained preparations. Studies of this process by light microscopy were originally misinterpreted and the process was considered to be a multiple division. Rosettes of this type are frequently found in cultures of trichomonads and trypanosomes. They are also relatively common in preparations of *T. gondii* collected during the acute phase of infection, when endodyogenies are often repeated inside parasitophorous vacuoles of macrophages and reticuloendothelial cells.

Multiple divisions

Multiple divisions are characteristic of amoebae, sporozoans, and Microspora, but are rarely observed in the other groups of parasitic protozoans. The formation of daughter cells by multiple divisions may be initiated by three main types of mother cells (Figure 32a–f).

A multinuclear type of mother cell may initiate multiple divisions. In this case, daughter cell formation starts at the end of a phase of repeated nuclear division in the mother cell. In this way, multinucleate plasmodia

are produced before cytoplasmic division starts. The occurrence of such multinucleate forms led to the naming of the genus *Plasmodium*. Multinucleate stages are also found in the life cycles of *E. histolytica*, in meronts and sporonts of gregarines, and in some stages of some coccidians. They occur in all gamonts of gregarines, but only in the microgamonts of some Coccidia. The cytoplasm of the plasmodia may or may not be divided, but when it is divided the pattern is always species specific. In eimerian and theilerian meronts and in the sporonts of hemosporidians and of some piroplasms, daughter cell formation closely follows the last nuclear division. In eimerian microgamonts, a microgamete is formed around each nucleus and an electro-

These may each develop: (1) two merozoites (some* Eimeria *spp.); (2) a single kinete (*Babesia *spp.); (3) many parasitic stages in the life cycle of various coccidians, i.e. merozoites of* Globidium *spp. or sporozoites of species of* Plasmodium, Babesia, *and* Theileria. *AN, axoneme (flagellum of microgamete); CT, cytomere; DA, daughter amoeba; DC, daughter cell; F, flagellum; KI, kinete; ME, merozoite anlage; MG, microgamont; MIG, microgamete; N, nucleus; NM, nucleus of microgamete (dense part); PN, polymorphous, multilobulated nucleus; RN, residual nucleus (light part); S, schizont.*

nlucent remnant of the mother cell's karyoplasm is left behind. Only occasionally do the nuclei of the mother cell divide after cytoplasmic division starts and therefore it is rare for two microgametes to originate from a single nucleus of the microgamont.

A uninuclear type of mother cell may initiate multiple division. In this case, daughter cell formation starts without a preceding phase of nuclear division, but the nucleus of the parasite has generally grown considerably and developed a lobulate surface before daughter cell formation occurs. When division of this giant nucleus begins, daughter cell formation occurs simultaneously. The daughter cells incorporate portions of the giant nucleus, the chromosomal components of which have been increased by a preceding endomitosis. This process of nuclear splitting occurs during the merogony of some cyst-forming coccidians and has been described as endopolygeny. The microgamonts of some species of *Sarcocystis* and of *Plasmodium* produce their microgametes in this way. A similar process of simultaneous nuclear splitting and daughter-cell formation is found in sporonts of some piroplasms during the production of sporozoites.

There is another type of multiple division that is intermediate between these two types. In these cases, a large mother cell with a lobated giant nucleus is divided into numerous uninuclear cytomeres. The single limiting membrane of these cytomeres originates from the surface membrane of the original cell or from the endoplasmic reticulum of the mother cell. Such cytomeres are regularly formed in meronts of some species of *Eimeria* such as *E. tenella*, in some species of *Globidium* and in sporonts of all species of *Babesia*, *Theileria*, *Plasmodium*, and *Hepatozoon*. The uninuclear cytomeres ultimately produce the daughter cells. They give rise to two merozoites in *Eimeria*, to a single kinete in *Babesia* and *Theileria*, to many merozoites in *Globidium*, and to sporozoites in *Plasmodium*, *Babesia*, and *Theileria*. Cytomeres merge in Myxozoa.

Additional information concerning the composition, metabolism, genetics, and molecular biology of the cell can be found in de Puytorac et al. (1987), Alberts et al. (2002), Darnell et al. (1994), Mehlhorn (2002), and Hausmann et al. (2003).

CONCLUSION

This chapter illustrates that the Protozoa are a heterogeneous group, with wide variations in morphology and life cycle. The parasitic protozoans are probably polyphyletic in origin and this is also probably true of the Eukaryota (see Classification and introduction to the parasitic protozoa). There is no good reason to assume that the Eukaryota are of a single evolutionary line, but rather they may have arisen by mutation and probably symbiosis from various prokaryotic predecessors at more than one time.

There are only a few features that are shared by all parasitic protozoans; they are all basically unicellular organisms and they are all eukaryotic. Based on their common unicellular eukaryotic plan, a vast array of forms has developed producing a wide variety of organisms. These organisms have successfully inhabited a great range of ecological niches, some of which, to our detriment, are located in the human or animal body (Mehlhorn 2002).

Kingdoms in dispute	4	References	13
Instability in the phyla and classes	5		
Genera and species: oases of stability	5		
Classification below the species level	7		

There are >200 000 named species of protozoa, of which nearly 10 000 are parasitic in invertebrates and in almost every species of vertebrate. It is therefore not surprising that humans should act as hosts to protozoa, but what is surprising is that we should harbor so many. During our short evolutionary history we have acquired >70 species belonging to >30 genera as heirlooms from our primate ancestors or souvenirs from the animals with which we have come in contact. Many of these protozoa are relatively harmless, but a few cause some of the most important diseases of tropical countries such as malaria, sleeping sickness, Chagas disease, and leishmaniasis, which together threaten over one quarter of the population of the world. Many also occur in temperate regions and some are increasingly being recognized and implicated as major pathogens in immunocompromised patients, particularly those suffering from HIV infections or undergoing immunosuppressive therapy.

From a practical viewpoint it is convenient to regard the protozoa as organisms that lie somewhere between the prokaryotic and higher eukaryotic organisms, sharing some of the characteristics of each. They are small, mostly 1–150 μm, the parasitic forms tending towards the lower end of this range, have short generation times, high rates of reproduction and a tendency to induce immunity to reinfection in those hosts that survive; features of infections with microparasites such as bacteria. On the other hand, protozoa are undoubtedly eukaryotic cells with organelles and metabolic pathways similar to those of their hosts.

Structurally, each protozoan is the equivalent of a single metazoan cell with its plasma membrane, nucleus, nuclear membrane, chromosomes, endoplasmic reticulum and, in most cases, mitochondria, Golgi body, ribosomes and various specialized structures adapted to meet particular needs (see Cellular organization of parasitic protozoa). Parasitic protozoa are not simple or degenerate forms and their particular adaptations frequently include complex life cycles and specialized ways of entering their hosts and maintaining themselves once they have gained access. Their nutrition, physiology, and biochemistry are largely geared to the parasitic habit and are specialized rather than degenerate. Sexual reproduction occurs in some protozoa and, in the parasitic forms, is particularly important in the sporozoans in which it provides for apparently limitless variation and adaptability.

NATURE OF THE PARASITIC PROTOZOA

The definition of Protozoa as single-celled eukaryotic organisms is very simplistic and the group has always been an enigmatic one, largely because of the small size of the cells, the relative lack of morphological features,

and the absence of any meaningful evolutionary history. In order to understand the background to the currently used classifications it is necessary to consider briefly the history of the subject, the changes that have occurred, and the reasons for these changes. It is generally agreed that the single-celled organisms that we now call protozoa were first recognized in 1676 by Antony van Leeuwenhoek, who described them as 'little animals' or 'animalcula' (Dobell 1960). The term Protozoa, meaning 'first animals', was introduced by Goldfuss in 1818 (Goldfuss 1818) and has been in use in a modified form ever since, although Goldfuss included a number of metazoans such as sponges and bryozoans within the group. The term 'single-celled animals' came into common usage after the botanist Matthias Jacob Schleiden and the zoologist Theodor Schwann had elucidated their cell theory in 1838 (see Cole 1926). By the middle of the 19th century, most biologists had realized that single-celled organisms included some that had greater affinities with plants than with animals and, in order to avoid the preconceptions inherent in the use of the term Protozoa, Hogg introduced the term 'Protoctista' to embrace those forms that had animal, plant, or no clear affinities (Hogg 1860). Haeckel also considered that all unicellular forms represented a primitive group for which he coined the term 'Protista' (Haeckel 1876). In 1938, Copeland grouped together all single-celled organisms that did not have obvious animal or plant affinities and used Haeckel's term Protista, which he later changed to Hogg's Protoctista on grounds of priority (Copeland 1938). All three terms, Protozoa, Protista, and Protoctista, are currently in use but this is not an appropriate place to discuss or to comment on the validity of these terms, the background of which is discussed in more detail by Lipscomb (1991) and Scamardella (1999). The term Protozoa is now almost universally used by parasitologists.

PARASITIC PROTOZOA AND PARASITIC INFECTIONS

Before attempting to classify the parasitic protozoa, it is necessary to introduce them and to comment briefly on the infections they cause. Traditionally, the parasitic protozoa of humans are listed in what used to be regarded as their taxonomic order but, as will be explained later, this is no longer appropriate. Nevertheless, listing them according to their normally accepted groupings is a convenient and familiar starting place.

Parasitic amoebae

Several species of amoebae are common in humans in most parts of the world but only one, *Entamoeba histolytica*, is an important pathogen. *E. histolytica* invades the small intestine and colon and may be carried to the liver and other parts of the body causing amoebic dysentery or liver abscesses. Four other intestinal amoebae are commonly found all over the world: *E. dispar*, once regarded as a nonpathogenic race of *E. histolytica*, resembles the pathogenic form; *E. coli*, the most common amoeba of humans, is a harmless commensal, as are *Endolimax nana* and *Iodamoeba butschlii*. Humans are occasionally infected with other intestinal amoebae, *E. hartmanni*, *E. moshkovskii*, and *E. chattoni*. *E. gingivalis* occurs in the mouth and is sometimes associated with infected gums.

BLASTOCYSTIS

Cysts of *Blastocystis hominis* are increasingly being recognized in human feces. At one time this protozoan was thought to be a simple contaminant of fecal samples but it is now known to infect the intestine where it occurs in several forms including amoeboid and cystic but not flagellated forms. *B. hominis*, which occupies an unique position in the classification of the protozoa, was not considered in the 9th edition of Topley and Wilson.

Facultative amoebae and flagellates of humans

Several free-living amoebae occasionally infect humans, sometimes with fatal results. Species of *Acanthamoeba* can cause upper respiratory tract infections in immunocompromised individuals. *Balamuthia mandrillaris* has been found in the brain. *Naegleria fowleri* and other *Naegleria* species, which are flagellates with amoeboid phases in their life cycles, have been implicated in primary meningoencephalitis in otherwise healthy individuals.

INTESTINAL AND RELATED FLAGELLATES

A number of flagellates occur in the alimentary canals of humans. Large infestations can build up, but the infections are seldom harmful although some may cause gastrointestinal disorders. Flagellates similar to those in the intestine can occur in other parts of the body, such as the urogenital system, and these may cause more serious infections. Eight species of flagellate are ubiquitous and common parasites of the human gastrointestinal tract or urogenital system. Few do any real harm, but some occasionally give rise to unpleasant symptoms which can usually be easily treated. The most important by far is *Giardia duodenalis*, also known as *G. lamblia*, *G. intestinalis*, or *Lamblia intestinalis*. Three species of trichomonads are common in all parts of the world: *Trichomonas vaginalis* in the vagina and urethra of women and in the urethra, seminal vesicles, and prostate of men; *T. tenax* in the mouth; and *Pentatrichomonas hominis* in the cecum and large intestine. *Enteromonas hominis* is cosmopolitan and harmless.

Chilomastix mesnili is rare and harmless. *Dientamoeba fragilis* is transmitted through the eggs of the pinworm *Enterobius vermicularis* and may cause diarrhea.

TRYPANOSOMES OF HUMANS IN SOUTH AMERICA

Trypanosoma cruzi occurs in South and Central America and is infective to c. 100–150 species of wild and domesticated mammals. The vectors are bugs belonging to the family *Reduviidae*. In the human host, the flagellated trypanosomes enter various cells, particularly macrophages, muscle cells, and nerve cells, where they round up and multiply as nonflagellated amastigote forms. The disease, which can last for the lifetime of the host, is called Chagas disease and takes various forms depending on where the amastigotes develop, the most serious consequences being cardiac failure due to parasites in the heart muscles or the loss of the nervous control of the alimentary canal due to parasites in the nervous system. *T. rangeli*, which is usually harmless, occurs in humans, primates, cats, and dogs in Central and South America where it is transmitted by bugs and, although the parasite is quite different from *T. cruzi*, the two are occasionally confused.

TRYPANOSOMES OF HUMANS IN AFRICA

The African trypanosomes are found in the blood and are transmitted from host to host by tsetse flies belonging to the genus *Glossina*. The only form found is the flagellated form and, unlike the New World species, there are no amastigote forms. Two forms (subspecies) infect humans; *Trypanosoma brucei gambiense* and *T. b. rhodesiense*, the former in West and Central Africa where it causes chronic sleeping sickness and the latter in the savannah of East Africa where it causes acute sleeping sickness. If the trypanosomes cross the blood–brain barrier they can cause coma and death. Closely related species occur in horses, cattle, and game animals.

LEISHMANIA SPECIES

Leishmania species, which are closely related to the trypanosomes, are transmitted by sandflies and cause serious diseases in humans. The parasites, which infect macrophages, occur only in the nonflagellated amastigote form. The typical infection is a long-lasting or nonhealing cutaneous lesion but in many species, and in particular individuals, the parasites may invade subcutaneous or deeper tissues, causing hideous and permanent disfiguration. The most serious disease, kala azar, involves the macrophages of organs such as the liver and can result in multiorgan system failure. Leishmaniasis is now known to be caused by a complex of about 20 species. As the morphology of all these parasites is similar, identification tends to be based on isoenzyme and DNA techniques. In the Old World, the main species causing cutaneous leishmaniasis are *L. tropica* and *L. major* and the species causing visceral leishmaniasis are *L. donovani* and *L. infantum*. In the New World cutaneous and mucocutaneous leishmaniasis are caused by at least 13 distinct species of *Leishmania* and visceral leishmaniasis is caused by *L. infantum* (at one time thought to be a separate species, *L. chagasi*, and now probably best referred to as *L. infantum chagasi*).

COCCIDIA: *TOXOPLASMA* AND RELATED COCCIDIA

Coccidia are common parasites of the epithelial cells of the gut of vertebrates. The most common species in humans is *Toxoplasma gondii*, a parasite of felids with a very wide range of intermediate hosts, including humans. In cats and other felids the life cycle is confined to the gut, but if the infective cysts passed in the feces are ingested by other warm blooded animals, multiplication occurs in various cells throughout the body. Infections are normally symptomless, but in the fetus or in immunosuppressed patients they may be very serious and they may occasionally cause ocular damage in healthy individuals. Humans also act as definitive hosts to two intestinal species related to *Toxoplasma*, *Sarcocystis hominis*, and *S. suihominis*, the respective intermediate hosts of which are pigs and cattle. Humans can also act as accidental, dead-end, intermediate hosts to several other species of *Sarcocystis*, cysts of which occur in the muscles. *Isospora belli* is another coccidian with a life cycle similar to that of *Toxoplasma* in cats but which occurs in the intestine of humans in which it is very rare.

CRYPTOSPORIDIUM

Coccidians belonging to the genus *Cryptosporidium* are relatively common parasites in the intestinal and respiratory tracts of mammals, birds, and reptiles. *C. parvum* causes gastrointestinal disorders in cattle, sheep, and humans. The infection is unpleasant but not normally dangerous in humans except in immunocompromised individuals, such as acquired immunodeficiency syndrome (AIDS) sufferers, in whom it can be fatal.

CYCLOSPORA

Cyclospora cayetanensis is an intestinal coccidian that causes a self-limiting infection with diarrhea and malabsorption. First recorded in 1986, it has since been found in both immunologically competent and immunocompromised patients in many parts of the world. The actual route of infection is unknown, although water and meat have been implicated. It is also not clear whether or not there is any other host apart from humans.

MALARIA PARASITES

The malaria parasites belong to the same phylum as the coccidians but to a different group, the hemosporidians, members of which, as the name implies, are parasitic in the erythrocytes of vertebrates. The malaria parasites of mammals all belong to the genus *Plasmodium* and are transmitted by female mosquitoes of the genus

Anopheles. Human malaria, one of the most important diseases in the world with >500 million people at risk in tropical and subtropical regions, especially Africa, is caused by four species of *Plasmodium*: *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. The disease is characterized by periodic fevers. *P. falciparum* causes malignant tertian malaria and is the most common and serious of all the forms of malaria, often causing cerebral damage resulting in death.

PIROPLASMS

The piroplasms are parasites of the erythrocytes of vertebrates and the vectors are ticks. *Babesia* species live in the blood of vertebrates and can cause serious disease, babesiosis. *B. microti* is common in wild rodents and occasionally infects humans in North America and sporadically elsewhere but the infections are not usually fatal. In Europe, splenectomized humans are sometimes infected with *B. divergens*, a cattle species, and the infection may be fatal.

CILIATES

Parasitic ciliates occur in most groups of vertebrates and invertebrates but only one species, *Balantidium coli*, infects humans. *Balantidium coli* is a common parasite of pigs in all parts of the world and has also been recorded in a number of other mammals including rats, dogs, camels, monkeys, apes, and c. 1 000 humans. The ciliate lives in the lumen of the large intestine and may invade the gut wall, where it produces ulcers resembling those caused by *Entamoeba histolytica*, although most cases are asymptomatic.

MICROSPORIDIANS

There are some 700 species of microsporidians in nearly all groups of vertebrates and invertebrates, particularly fish and arthropods. All microsporidians possess an inherent ability to multiply in their vertebrate hosts but this seems to be curtailed in humans, except in those individuals whose immune system is compromised. The first human case of microsporidiosis was recorded in 1959 and since then several new genera and species have been recorded, mainly in AIDS sufferers and others undergoing immunosuppressive therapy. Microsporidiosis is extremely rare in humans. *Encephalitozoon cuniculi*, a parasite of peritoneal macrophages that also spreads to other parts of the body including the brain, occurs in rodents, rabbits, dogs, and other carnivores and primates and there are increasing numbers of records from humans. Of the other species, few have been recorded from any animals although these must almost certainly be the sources of human infection. *Encephalitozoon hellem* parasitizes the cornea and conjunctiva and has been recorded in the viscera. *Encephalitozoon intestinalis* is an intestinal form that also occurs in a variety of cells in different parts of the body. *Enterocytozoon bieneusi* is also an intestinal form associated with chronic diarrhea in AIDS patients. *Vittaforma corneae* infects the cornea. *Trachipleistophora hominis* has been recorded from the cornea and skeletal muscle of AIDS patients. The microsporidians are now thought to be more closely related to the fungi than the protozoa, but are retained in this volume because this is where they have been traditionally placed.

PNEUMOCYSTIS

The taxonomic position of *Pneumocystis* has long been uncertain but it is now clearly acknowledged to be a fungus (see Cavalier-Smith 2001). *Pneumocystis carinii*, which is normally a harmless parasite in the lungs but may be fatal in immunocompromised people, has previously been regarded as a protozoan and was included in this volume in the 9th edition of Topley and Wilson. In the present edition it is considered with the other fungi in the Medical Mycology volume,

Pneumocystis pnuemonia.

KINGDOMS IN DISPUTE

In his 1758 classification of all living things, Carl Linnaeus recognized two kingdoms, Animalia and Plantae. By the middle of the 19th century, Hogg (1860) and Haeckel (1876) had argued for the creation of an additional kingdom to accommodate single-celled organisms. Haeckel is often credited with the concept of three kingdoms of living things: Animalia (animals), Plantae (plants), and Protista (protozoa), which was expanded to four kingdoms, Animalia, Plantae, Protoctista, and Mychota (prokaryote organisms) by Copeland (1938). With the removal of the fungi from the plant kingdom the erection of a fifth kingdom, Fungi, was necessary and the viruses were added by Jahn and Jahn (1949) who recognized six kingdoms: Archetista (viruses), Monera (bacteria and blue green algae), Metazoa (multicellular animals), Metaphyta (multicellular plants), Fungi (fungi), and Protista (unicellular organisms). This classification did not recognize the fact that the single-celled eukaryotic organisms were not a homogeneous assemblage and that there were unicellular members in the animal and plant kingdoms that could not logically be separated from the Metazoa and Metaphyta. In other words, there was an argument for the creation of groupings such as Protozoa and Protophyta within the animal and plant kingdoms. Nevertheless, Jahn and Jahn's classification became widely adopted. With the removal of the viruses, now considered to be nonliving, there emerged what is now known as Whittaker's five-kingdom classification: Monera (prokaryotes), Animalia, Plantae, Fungi, and Protista (Whittaker 1969). Whittaker's five-kingdom scheme has stood the test of time fairly well but, as studies at the biochemical and molecular levels identified an increasing number of problems with the conventional ideas about single-celled

organisms, it became necessary to adopt a rather more radical approach such as that set out by Cavalier-Smith (1993) and largely adopted by Corliss (1994). Conventionally, since the time of Linnaeus, the term 'kingdom' has been used as the highest category in the taxonomic hierarchy but Corliss, echoing the views of many protozoologists, accepted that the 'lower' eukaryotes could no longer be accommodated within a single kingdom and advocated the use of a superior category, the 'Empire,' containing six eukaryote kingdoms: Archezoa, Protozoa, Chromista (unicellular plant-like organisms), Plantae, Fungi, and Animalia. The first three contain only single-celled organisms, but a number of single-celled organisms also occur in the kingdom Plantae, a few in the kingdom Fungi, but none in the kingdom Animalia. One problem was that in this classification the kingdom Protozoa was not equivalent to any previous grouping with that name. In 1998, Cavalier-Smith came down in favor of six kingdoms – Bacteria, Protozoa, Chromista, Plantae, Fungi, and Animalia – effectively separating the protozoa from both the plant and animal kingdoms (Cavalier-Smith 1998). This broad classification will be adopted in this chapter.

INSTABILITY IN THE PHYLA AND CLASSES

When the Animalia was recognized as a kingdom, the Protozoa could be classified as a phylum and the subordinate groups as classes. However, when the status of the Protozoa was raised to that of a kingdom, the subordinate groups automatically became phyla and certain groups that had previously enjoyed ordinal status became elevated to classes or even phyla. This caused a great deal of confusion and requires some explanation. Goldfuss (1818) recognized three great groups of protozoa (amoebae, flagellates, and ciliates) on the basis of their mode of locomotion and this number was increased to four by the addition of the sporozoans by Bütschli (1883–5). These four groups persisted in various guises until comparatively recently, as the Rhizopoda or Sarcodina (amoebae, protozoa that move by means of pseudopodia), Mastigophora (flagellates, protozoa that move by means of flagella), Ciliophora or Ciliata (ciliates, protozoa that move by means of cilia), and Sporozoa (sporozoans, spore-forming protozoa that do not have any obvious means of locomotion). The Sporozoa sometimes included microsporidians and myxosporidians, often grouped together as cnidosporidians. This is essentially the traditional classification used in classical works by Calkins (1901), Craig (1926), Wenyon (1926), Kudo (1954), and Manwell (1961). By the beginning of the 1960s, with the availability of increasingly sophisticated ways of studying protozoa, it was becoming clear that this classification was unworkable and in 1964 the Society of Protozoologists published a revised classification (Honigberg et al. 1964). This grouped the Sarcodina and Mastigophora together as the Sarcomastigophora and removed the myxosporidians and microsporidians from the Sporozoa, with which they had been traditionally classified. One particularly controversial action was to remove the piroplasms from the Sporozoa and place them among the Sarcomastigophora, something that was ignored by virtually all parasitologists. The Society of Protozoologists' 1964 classification, with slight modifications (e.g. the replacement of the piroplasms among the Sporozoa) was widely accepted and appeared in standard textbooks such as those by Baker (1969) and Levine (1973). Subsequent changes involving *Toxoplasma* and related organisms were gradually incorporated into the 1964 scheme and a consensus classification, such as that of Baker (1977), gradually emerged.

This consensus did not last long, and rapid and major developments in our understanding of the protozoa necessitated a new classification. In 1980, the Society of Protozoologists published its second classification (Levine et al. 1980). The working party responsible for this classification recognized that the protozoa did not represent an assemblage of primitive organisms but embraced a number of diverse and distinct groups, and recognized seven phyla: Sarcomastigophora, Apicomplexa (essentially equivalent to the Sporozoa), Ciliophora, Microspora, Myxozoa, Ascetospora, and Labyrinthomorpha. Nevertheless, the affinities with the traditional classification remained clear and a modification which took into account only the parasitic forms was set out by Cox (1981) and used in information retrieval systems and parasitology textbooks such as Cox (1982), Kreier and Baker (1987), and Mehlhorn (1988). Like its predecessors, this scheme failed to keep up with developments at the ultrastructural, molecular, and biochemical levels and by the beginning of the 1990s Sleigh (1991) had decided to ignore the concept of phyla and simply recognize four 'groups': the flagellated protozoa, the amoeboid protozoa, the ciliated protozoa, and the sporozoans. This approach, also adopted by Cox (1991, 1993), has the merit of simplicity and clear links with the traditional classification, but is merely a classification of convenience and does not stand up to rigorous analysis at either the evolutionary or molecular level.

GENERA AND SPECIES: OASES OF STABILITY

The names of the genera and species of protozoa that infect humans have remained remarkably consistent throughout the upheavals that have characterized the classification of the protozoa over the past few years. The main changes have been the addition of the coccidians *Cryptosporidium* and *Cyclospora*, largely as concomitants of HIV infections, *Balamuthia* as an accidental infection, and *Blastocystis*. In addition, previously unidentified tissue parasites have now been identified as *Sarcocystis* spp. Another important change has been the

growth in the number of species in the genus *Leishmania*. More recently we have seen the removal of the enigmatic species *Pneumocystis carinii*, now classified among the fungi, and the microsporidians *Brachiola*, *Encephalitozoon*, *Enterocytozoon*, *Microsporidium*, *Nosema*, *Septata*, and *Trachipleistophora*, which now rightly belong with the fungi but are retained in this volume for the sake of continuity.

The increase in the number of parasitic protozoa recorded from humans and the accumulation of knowledge about their biology has resulted in the creation of taxonomic and other groupings at the subgenus and subspecies levels, largely as a result of an unwillingness to tamper with well-established genera and species. As the parasitic protozoa have traditionally been classified with the animal kingdom, the International Code of Zoological Nomenclature applies to the naming of the subordinate groups, subgenera, and subspecies. However, the rules have not been applied rigorously and several apparent anomalies have arisen and the use of subgenera, species, and subspecies across the whole of the parasitic protozoa has not been uniform.

Among the amoebae, the only controversy relates to the most important parasite, *Entamoeba histolytica*. For many years it has been known that this parasite exists in two forms, one pathogenic and one nonpathogenic. This has resulted in some workers suggesting that the pathogenic form sensu strictu should be called *E. histolytica* and the nonpathogenic form something different, for example *E. dispar* as suggested by Brumpt (1925). Until relatively recently, most scientists were content to use one name, *E. histolytica*, but isoenzyme and other biochemical and molecular studies have established that there are real differences between the pathogenic and nonpathogenic forms and this has resulted in the reintroduction of *E. dispar* for the nonpathogenic form. Unfortunately, things are not that simple, and there have been reports that some of the biochemical criteria used are not stable (Spice and Ackers 1992). Nevertheless, it seems sensible to use the two specific names for which there is some precedent. Another apparently harmless species resembling *E. histolytica* is *E. hartmanni*, and there have been occasional reports of infections with another similar parasite, *E. moshkovskii*. There is currently some stability in the classification of amoebae belonging to the genus *Entamoeba*, but there may be other revisions on the way.

Giardia duodenalis is another intestinal parasite that causes a range of symptoms and what actually constitutes this species remains to be resolved, mainly because of the genetic variability that exists even within cloned lines (Thompson et al. 1993). There is little agreement about what the species name should actually be: *G. intestinalis* and *G. duodenalis* tend to be used interchangeably in western Europe and Australia, *G. lamblia* is used in the USA, and *Lamblia intestinalis* is sometimes used in eastern Europe. Electrophoretic analysis suggests that the species in humans is morphologically *G. duodenalis*, which parasitizes a number of mammals, but that it could be afforded specific status as *G. intestinalis* on grounds of host specificity (Mayrhofer et al. 1995).

The genus *Leishmania* has received the most attention. Originally there were two Old World species, the cutaneous form *L. tropica* and the visceral form *L. donovani*. *L. tropica* was subsequently differentiated as two varieties, *L. tropica* var. *minor* and *L. tropica* var. *major*, and later subspecies, *L. t. minor* and *L. t. major*, which have now been raised to species level as *L. tropica* and *L. major*. Two subspecies of *L. donovani*, *L. d. donovani* and *L. d. infantum*, have now been raised to species level, as has *L. donovani* var. *archibaldi*. It was originally thought that the leishmanias in the New World were varieties of the Old World forms and the cutaneous form was called *L. tropica* var. *mexicana*, later changed to *L. mexicana*, and the mucocutaneous form was called *L. tropica* var. *braziliensis*, subsequently *L. braziliensis*. The New World visceral form of *L. donovani* subsequently became *L. d. chagasi* and then *L. chagasi*, but is now thought to be the same as the Old World species *L. infantum* (Maurício et al. 2000) which, in this volume, is referred to as a subspecies, *L. infantum chagasi*. The cutaneous forms have undergone massive revisions as more and more subspecies or species have been discovered. Initially, each new discovery was assigned either to *L. mexicana* or to *L. braziliensis* as a subspecies, for example *L. b. braziliensis*, but current opinion favors the use of species. Recognition of the fact that these species could and should be grouped as the 'mexicana complex' and the 'braziliensis complex' led to the creation of two subgenera; *Leishmania*, which embraces all the Old World species and members of the 'mexicana complex' and *Viannia*, which includes the 'braziliensis complex.' A detailed account of this classification and its background is given by Lainson and Shaw (1987). It should be pointed out here that the classification of the New World leishmanias is now based on morphological, behavioral, geographical, clinical, biochemical, and molecular criteria (see also New World leishmaniasis).

Subgenera have also been used for the classification of the trypanosomes, *Trypanosoma* spp. Large numbers of trypanosomes parasitize all groups of vertebrates and, in an attempt to put some kind of order into what was becoming an increasingly heterogeneous genus, Hoare, in 1966, proposed the creation of a number of subgenera as a framework within which to classify the trypanosomes of mammals (see Hoare 1972). These subgenera were placed in two major groups; Stercoraria, containing *Megatrypanum*, *Herpetosoma*, and *Schizotrypanum*, and Salivaria, containing *Duttonella*, *Nannomonas*, *Pycnomonas*, and *Trypanozoon*. The New World trypanosome of humans, *T. cruzi*, is classified in the subgenus *Schizotrypanum* and *T. rangeli* is placed in the subgenus

Herpetosoma, whereas the Old World forms, *T. brucei gambiense* and *T. b. rhodesiense*, are placed in the subgenus *Trypanozoon* (see for example Lumsden and Evans 1976). However, the use of *Trypanosoma (Schizotrypanum) cruzi* and *Trypanosoma (Trypanozoon) brucei* is clumsy and the practice has now been all but abandoned.

The classification and nomenclature of the human trypanosomes is still not entirely satisfactory at the level of genus and species. There are real differences between *T. cruzi* and *T. brucei* and, although it would seem logical to classify them as separate genera, this cannot be done in isolation. Any changes would result in serious consequences for the classification of all the other trypanosomes of vertebrates and great disruption to information retrieval systems if one of the two generic names were to change.

The malaria parasites belonging to the genus *Plasmodium* have also been classified into subgenera largely on the same grounds as the trypanosomes; the numbers recorded in all groups of higher vertebrates, and a perceived need to bring some order into an increasingly complex situation. Nine subgenera have been proposed: *Plasmodium*, *Vinckeia*, *Laverania*, *Haemamoeba*, *Giovannolaia*, *Noyella*, *Huffia*, *Sauramoeba*, and *Carinia*, of which three occur in mammals, four in birds, and two in lizards (Garnham 1966). The human species, *Plasmodium falciparum*, was placed in the subgenus *Laverania* whereas the others, *P. malariae*, *P. ovale*, and *P. vivax*, were placed in the subgenus *Plasmodium*. As far as human parasites are concerned, the use of subgenera served very little purpose and has fallen into disuse.

CLASSIFICATION BELOW THE SPECIES LEVEL

There is a perceived need for some sort of category below that of species to differentiate between genetically distinct forms of parasites that produce markedly different diseases in humans, and the use of subspecies has been common among protozoologists. In the genus *Leishmania*, in which it was most widely used, this practice has fallen into disuse and there has been an incremental drift upwards towards separate species status. This tendency has been resisted by those working with the African trypanosomes and *Trypanosoma cruzi*, the causative agent of Chagas disease in South America. There is no doubt, however, that there are many different forms of *T. cruzi* and that their epidemiology and the diseases they produce are significantly different but, although there seems to be a de facto case for the consideration of subspecies, there has been little enthusiasm for such a move.

The only consistent use of subspecies is in the case of the African trypanosomes. Human sleeping sickness in Africa is caused by two different trypanosomes both closely related to a natural parasite of equines and game, *Trypanosoma brucei*. The two human forms have sometimes been recognized as species, *T .gambiense* and *T. rhodesiense* (Levine 1973) but, using morphological, clinical, epidemiological, biochemical, and molecular criteria, there can be no doubt about the close relationship between the human and the animal forms and the logical conclusion is that the animal form should be classified as *Trypanosoma brucei brucei* and the human forms as *T. brucei gambiense* and *T. brucei rhodesiense*. This approach has been adopted by most workers in the field and by information retrieval services. The widespread use of these subspecies was partly responsible for the demise of the use of subgenera because most authors and editors did not want to be bothered with names like *Trypanosoma (Trypanozoon) brucei gambiense*.

Toxoplasma gondii is another parasite that seems to exist in two forms, a virulent one and an avirulent one, and it is also very interesting to note that a single strain of *T. gondii* probably accounts for all the virulent forms worldwide (Sibley and Boothroyd 1992). There are, however, no serious moves to create any subspecies.

MOLECULAR AND BIOCHEMICAL APPROACHES TO THE CLASSIFICATION OF THE PARASITIC PROTOZOA

Fortunately there are a number of alternative approaches other than morphology and life cycles to the classification of protozoa, including the application of the techniques of biochemistry and molecular biology. Such techniques are increasingly being used to resolve phylogenetic, and consequently taxonomic, questions. The most widely used techniques can be roughly divided into those that are enzymatic or genetic. This topic is too extensive to be discussed in detail here and there is a useful review by Barta (2001), a comprehensive phylogenetic tree of parasites by de Meeŭs and Renaud (2002), and accounts of particular applications in a number of papers in a symposium volume mainly devoted to leishmaniasis (Alvar and Baker 2002).

The first widely used technique was the use of isoenzyme profiles, which proved to be extremely useful tools for distinguishing between apparently identical parasites. Isoenzymes are enzymes that perform the same functions but have different mobilities in electric fields and can thus be distinguished very easily; populations of parasites with identical isoenzyme patterns are called zymodemes. This technique has been successfully used to distinguish the various species of *Leishmania* and the results obtained have correlated well with epidemiological, clinical, and molecular findings. Isoenzymes have also been used to distinguish between the subspecies of African trypanosomes and pathogenic and nonpathogenic forms of *Entamoeba histolytica* and *Toxoplasma gondii*, and have also been used extensively in studies on *Giardia duodenalis* and *Cryptosporidium parvum*.

Useful as they may be, isoenzyme techniques have the major disadvantage of being reliable only for distinguishing between organisms that are closely related (Richardson et al. 1986) and DNA and RNA technology is increasingly being used both for the diagnosis of parasitic infections and for resolving taxonomic and phylogenetic problems. Briefly, both DNA and RNA can be used to determine evolutionary distances, as nucleotide sequences tend to diverge over time and to evolve at a more predictable rate than do morphological characters. Differences in nucleotide sequences can, therefore, be compared and the more similar the sequences in two organisms the more likely it is that they are related; large numbers of such studies can be used to create realistic phylogenetic trees. Different kinds of RNA, particularly small nuclear RNA (16S and 18S SnRNA) and small subunit ribosomal RNA (SSUrRNA) have been extensively used for taxonomic and phylogenetic investigations and, although data are currently based on very few taxa, these techniques have been very useful. Johnson and Baverstock (1989) were the first to attempt to produce a comprehensive phylogenetic tree of the protozoa with special reference to the parasitic forms, using data derived from SSUrRNA. RNA sequences have confirmed the differences between pathogenic and nonpathogenic strains of *E. histolytica* determined by isoenzyme studies (Petri et al. 1993). Similar studies have also identified similarities between the Old World trypanosome *T. cruzi* and New World *T. brucei* and have distanced both from *Leishmania* species, thus confirming the current classification of the kinetoplastid flagellates (Maslov and Simpson 1995). SSUrRNA are the most commonly used sequences employed in systematic studies and, as far as the protozoa are concerned, the validity of such studies has been confirmed by comparing results obtained with SSUrRNA and those obtained using amino acid sequences of protein-encoding genes (Baldauf et al. 2000).

Ribosomal RNA studies using 18S rRNA have also shown that *Toxoplasma* and *Sarcocystis* are monophyletic and thus derived from a common ancestor (Ellis et al. 1995).

DNA methodology has also proved to be very useful. DNA probes have been extensively used for studies on *Leishmania* species both for diagnosis and for determining relationships. Initial studies that distinguished between the New World forms *L. mexicana* and *L. braziliensis* have now been extended to all species and, coupled with isoenzyme studies, have been largely responsible for the present classification of the genus. The development of the polymerase chain reaction (PCR) has revolutionized the use of DNA techniques in parasitology and has been used to confirm the existence of virulent and avirulent strains of *T. gondii* (Guo and Johnson 1995). Other widely used techniques include restriction fragment length polymorphism (RFLP) and random amplification of polymorphic DNA (RAPD). One example of the application of such techniques has been the establishment of the fact that *Leishmania chagasi* in the New World is the same as *L. infantum* in the New World (Maurício et al. 2000).

Increasingly, biochemical and molecular criteria are being used for the identification of new species and it is now unlikely that any future descriptions of protozoa lacking good morphological characteristics will be published and accepted unless the descriptions are soundly based at the molecular and genetic levels.

No matter how carefully any one particular species is characterized, this is of little use to any overall classification, which needs to take into account the characteristics of a diversity of organisms. One of the most powerful tools available for the study of evolution is parsimony analysis (Sober 1988; Stewart 1993). Essentially what this means is that the simplest explanation consistent with the available data should be used to reach conclusions about phylogenetic relationships. The concept is not a new one and many biologists are familiar with it in another guise, that of Occam's razor, which holds that entities should not be multiplied beyond necessity, i.e. where there is a simple explanation there is no need to look for a complex one. Parsimony analysis relies on the availability of raw data and, in the phylogenetic studies with which we are concerned here, these include morphology, life cycles, and molecular data. The ideal is to create taxa that can be ranked in a hierarchical order that reflects the underlying phylogeny. This approach has obvious advantages but also less obvious disadvantages: two taxa may possess characters that are only superficially similar; too much emphasis may be placed on too few examples; and the rates of morphological or molecular change may not be the same in the different groups under consideration. The most satisfactory examples of parsimony analysis are where traditional and molecular approaches produce the same overall pattern, but these may present the greatest difficulties if the various criteria used (e.g. morphological and molecular) are both based on the same invalid assumptions. On the other hand, where different approaches produce conflicting results it is possible that in seeking an explanation for the discrepancies a better understanding of the relationships will emerge.

CLASSIFICATION OF THE PARASITIC PROTOZOA OF HUMANS

In recent years, the availability of a number of molecular markers has made it possible to analyze relationships between protozoans and to draw conclusions that would not have been possible using morphological characters alone. So far, there has been remarkable agreement between the different approaches and, in most cases, molecular techniques have confirmed the more traditional findings; in other cases they have clarified

long-standing controversies. In the long run, it is likely that molecular classifications of the protozoa will be the norm. What most parasitologists require, however, is a convenient, familiar, and stable framework within which to work and communicate, as most are concerned with only relatively few species of protozoa and those interested in the parasitic protozoa of humans need to be familiar with only around 20 genera and 50 species. It is therefore important that any classification should reflect modern thinking about the classification of the protozoa as a whole, while retaining sufficient traditional material to permit easy reference to past papers, textbooks, and information retrieval systems. There have been a number of attempts to do this and it is convenient to consider three classifications, those of the 1980s, 1994, and 2000s. The 1980s classifications are largely based on the Society of Protozoologists' second classification (Levine et al. 1980), the 1994 classifications are represented by the interim classification of Corliss (1994), and the 2000s classification is based on the comprehensive system drawn up by Cavalier-Smith (1993) and subsequent modifications. The 1980 and 1994 systems are set out below in order to set the scene for the more recent classification and to provide some continuity between the different systems several of which are still in use.

Traditional 1980s classification

Below is an outline version of a traditional 1980s classification. This classification is provided simply as a background for further discussion and to focus on the central problem of protozoan classification; the need to satisfy protozoologists on one hand and the need to be useful to parasitologists, especially medical parasitologists, on the other. The detailed classification by Lee et al. (1985) is typical of those used in the 1980s.

Kingdom Animalia
Subkingdom Protozoa
Phylum Sarcomastigophora (the amoebae and flagellates)
Subphylum Mastigophora. Intestinal, tissue, and blood-dwelling flagellates, e.g. *Giardia*, *Chilomastix*, *Trichomonas*, *Dientamoeba*, *Leishmania*, *Trypanosoma*
Subphylum Sarcodina. Obligate and facultative amoebae, e.g. *Entamoeba*, *Iodamoeba*, *Endolimax*, *Acanthamoeba*, *Naegleria*
Phylum Apicomplexa (the sporozoans)
Class Sporozoea
Subclass Coccidia
Order Eucoccidiida
Suborder Eimeriina, e.g. *Isospora*, *Sarcocystis*, *Toxoplasma*, *Cryptosporidium*
Suborder Haemosporina, e.g. *Plasmodium*
Subclass Piroplasmea, e.g. *Babesia*
Phylum Microspora, e.g. *Encephalitozoon*, *Nosema*
Phylum Ciliophora, e.g. *Balantidium*

1994 'Interim user-friendly classification'

In 1994, in order to meet various and sometimes conflicting requirements, Corliss proposed a 'utilitarian and user-friendly classification' which took into account the numerous advances that had been made since the 1980 classifications while maintaining much that was traditional (Corliss 1994). In this classification, Corliss recognizes six kingdoms with the majority of single-celled organisms generally accepted as protozoa in two of them, the Archezoa and Protozoa. In the Archezoa there are three phyla, two of which contain parasites, and in the Protozoa there are 14 phyla, six of which contain parasites. This classification, which is outlined below, was accepted by a majority of protozoologists and was used in the 9th edition of Topley and Wilson.

Empire Eukaryota
Kingdom Archezoa
Phylum Metamonada
Class Trepomonadea
Order Diplomonadida, e.g. *Giardia*
Order Enteromonadida, e.g. *Enteromonas*
Class Retortamonadea
Order Retortamonadida, e.g. *Chilomastix*, *Retortamonas*
Phylum Microspora
Class Microsporea
Order Microsporida, e.g. *Encephalitozoon*, *Enterocytozoon*, *Nosema*
Kingdom Protozoa
Phylum Percolozoa
Class Heterolobosea
Order Schizopyrenida, e.g. *Naegleria*
Phylum Parabasala
Class Trichomonadea
Order Trichomonadida, e.g. *Dientamoeba*, *Trichomonas*
Phylum Euglenozoa
Class Kinetoplastidea
Order Trypanosomatida, e.g. *Leishmania*, *Trypanosoma*
Phylum Ciliophora
Class Litostomatea
Order Trichomonatida, e.g. *Balantidium*
Phylum Apicomplexa (Sporozoa)
Class Coccidea
Order Eimeriida e.g. *Cryptosporidium*, *Cyclospora*, *Isospora*, *Sarcocystis*, *Toxoplasma*
Class Haematozoea
Order Haemosporida, e.g. *Plasmodium*
Order Piroplasmida, e.g. *Babesia*
Phylum Rhizopoda
Class Lobosea
Order Acanthopodida, e.g. *Acanthamoeba*, *Balamuthia*
Class Entamoebidea

Order Euamoebida, e.g. *Endolimax*, *Entamoeba*, *Iodamoeba*

Kingdom Chromista

Kingdom Plantae (the plant kingdom sensu strictu)

Kingdom Fungi (the fungi sensu strictu)

Kingdom Animalia (the animal kingdom sensu strictu)

This classification retained many of the familiar features of more traditional classifications and served as a transitional phase between the older classifications and the newer ones outlined below.

2000s Classification

Although the Corliss classification served the protozoological community well, subsequent developments in molecular biology have provided us with a much clearer understanding of phylogenetic relationships involving the single-celled organisms, to such an extent that the status of the various groups of protozoa has had to be reappraised. Comparison of SSUrRNA and protein sequences (Sogin and Silberman 1998; Doolittle 1999; Baldauf et al. 2000) have made it possible to arrange organisms within groups based on evolutionary distances. Such studies by themselves, however, do not necessarily reflect hierarchical arrangements. An alternative approach has been to consider the megaevolution of eukaryotic organisms, particularly the acquisition of prokaryotic organelles, for example mitochondria and chloroplasts, by a process of symbiogenesis,. Such studies, coupled with the realization that organelles can have been not only acquired but also modified, multiplied, or lost, have made it possible to arrange all living organisms within a realistic and evolutionarily and taxonomically sound overall system (Cavalier-Smith 1998). It is also clear that RNA and protein sequences broadly reflect the hierarchical systems based on evolutionary principles, thus providing, for the first time, a system of classification of the protozoa that is comparable with systems devised for higher eukaryotes. This scheme will therefore be adopted here and the major elements are easily recognizable as those in earlier classifications. In this classification there are six kingdoms – Bacteria, Protozoa, Animalia, Fungi, Plantae, and Chromista – of which the Protozoa constitute the basal eukaryotic kingdom. This system re-establishes the validity of the kingdom Protozoa with 13 phyla of which seven contain parasites that infect humans, but has necessitated the redistribution of some taxa, including some parasites of humans.

KINGDOM PROTOZOA. Unicellular eukaryotic phagotrophic, nonphotosynthetic organisms without cell walls

Subkingdom 1 Archezoa. Single-celled eukaryotic organisms exhibiting various prokaryotic features in their ribosomes and tRNA; lacking plastids, mitochondria, Golgi bodies, and cytoplasmic inclusions, e.g. hydrogenosomes and peroxisomes.

Phylum Metamonada. Unicellular intestinal flagellates with two, four or eight (occasionally more) flagella.

Class Trepomonadea. Intestinal flagellates; one or two karyomastigonts each with one to four flagella; no contractile axostyle; few cell-surface cortical microtubules.

Order Diplomonadida: *Giardia duodenalis*

Order Enteromonadida: *Enteromonas hominis*

Class Retortamonadea. Intestinal flagellates; cortical microtubules over entire body surface

Order Retortamonadida *Chilomastix mesnili*, *Retortamonas intestinalis*

Phylum Parabasalia. Unicellular flagellates with one or more nuclei and numerous flagella; characteristic complex parabasal body equivalent to Golgi body; no mitochondria.

Class Trichomonadea. Intestinal and related flagellates; typically four to six flagella, noncontractile axostyle.

Order Trichomonadida: *Dientamoeba fragilis*, *Trichomonas vaginalis*, *T. tenax*, *Pentatrichomonas hominis*

Subkingdom 2 Neozoa. Single-celled eukaryotic organisms typically possessing plastids, mitochondria, Golgi bodies, and cytoplasmic inclusions including hydrogenosomes and peroxisomes.

Phylum Percolozoa. Unicellular, nonpigmented organisms typically possessing one to four flagella, mitochondria and peroxisomes but lacking Golgi bodies.

Class Heterolobosea (flagellated amoebae). Amoeboflagellates; trophic form amoeboid; temporary flagellated phase in life cycle.

Order Schizopyrenida: *Naegleria fowleri*

Phylum Euglenozoa. Unicellular flagellates with one to four flagella, possess Golgi body and mitochondria.

Class Kinetoplastea (kinetoplastid flagellates). Unicellular flagellates with one to two flagella; prominent kinetoplast (DNA-containing body) within a single mitochondrion.

Order Trypanosomatida: *Leishmania donovani*, *L. infantum*, *L. major*, *L. tropica*, *L. braziliensis*, *L. mexicana*, *L. aethiopica*, *L. amazonensis*, *L. colombiensis*, *L. garnhami*, *L. guyanensis*, *L. lainsoni*, *L. lindenbergi*, *L. naiffi*, *L. panamensis*, *L. peruviana*, *L. pifanoi*, *L. shawi*, *Trypanosoma cruzi*, *T. brucei gambiense*, *T. brucei rhodesiense*, *T. rangeli*

Phylum Amoebozoa. Unicellular nonflagellated organisms with pseudopodia used for both feeding and locomotion.

Class Amoebaea. Amoebae with lobose pseudopodia and mitochondria; typically free-living but facultative parasites.

Order Acanthopodida: *Acanthamoeba castellani*, *Acanthamoeba* spp., *Balamuthia mandrillaris*

Class Entamoebidea. Amoebae with lobose pseudopodia; secondary loss of mitochondria, peroxisomes or hydrogenosomes; obligate parasites.

Order Euamoebida: *Entamoeba histolytica*, *E. coli*, *E. dispar*, *E. hartmanni*, *E. gingivalis*, *E. moshkovskii*, *E. chattoni* (=*E. polecki*), *Endolimax nana*, *Iodamoeba buetschlii*

Phylum Sporozoa (sporozoans). Unicellular organisms possessing at some stage an apical complex composed of polar rings, rhoptries, micronemes, and typically a conoid; elaborate life cycles involving a sexual process; all parasites.

Class Coccidea. Sexual stages small and intracellular usually in epithelial cells of vertebrate host; resistant oocyst.

Order Eimeriida: *Cryptosporidium parvum*, *Toxoplasma gondii*, *Cyclospora cayetanensis*, *Isospora belli*, *Sarcocystis hominis*, *S. suihominis*

Order Piroplasmida: *Babesia microti*, *B. divergens*, *B. gibsoni*

Order Haemosporida: *Plasmodium falciparum*, *P. malariae*, *P. ovale*, *P. vivax*

Phylum Ciliophora (ciliates). Unicellular organisms characterized by possession of many cilia used for locomotion and with complex oral ciliature used for feeding; two kinds of nuclei, one or more polyploid macronuclei and one or more diploid micronuclei.

Class Litostomatea. Mainly free-living ciliates with inconspicuous oral ciliature.

Order Vestibuliferida: *Balantidium coli*

KINGDOM CHROMISTA. Unicellular photosynthetic filamentous or colonial, organisms (in part 'algae'); some with secondary loss of plastids.

Subkingdom Chromobiota

Phylum Bigyra

Class Blastocystea: *Blastocystis hominis*

KINGDOM FUNGI. Eukaryotic heterotrophic organisms lacking plastids but possessing cell walls containing chitin and β-glycans.

Phylum Microspora (Microsporidians)

Class Microsporea: *Encephalitozoon cuniculi*, *E. hellem*, *E. intestinalis*, *Enterocytozoon bieneusi*, *Nosema ocularum*, *N. corneum*, *Brachiola connori*, *B. vesicularum*, *B. algerae*, *Microsporidium ceylonensis*, *M. africanum*, *Vittaforma corneae*, *Trachipleistophora hominis*, *T. anthropophthera*, *Pleistophora ronneafiei*.

KINGDOMS AND SUBKINGDOMS

The most important change from the 1980 and 1994 classification is that the Protozoa becomes a kingdom in its own right and is no longer regarded as a subkingdom of the kingdom Animalia as in the 1980s classification. The kingdom Protozoa now embraces the 1994 kingdoms Archezoa and Protozoa and it is now accepted that the kingdom Protozoa is the basal eukaryotic kingdom and has equal status with the other eukaryotic kingdoms, Chromista, Fungi, Plantae, and Animalia. As far as parasitologists are concerned this move is to be welcomed as it brings together most of the single-celled organisms traditionally regarded as protozoa within a single higher taxon.

ARCHEZOA

In the Corliss 1994 classification it was recognized that the flagellated protozoa, far from being classified in the same phylum as the amoebae as in the 1980s classification, did not constitute a coherent group and needed to be separated in some logical way. A number of amitochondrial flagellates and amoebae, together with the microsporidians, were placed in a distinct primitive kingdom, the Archezoa, the affinities of which were at that time obscure. In the present classification, the subkingdom Archezoa retains the phylum Metamonada and has added to it the phylum Parabasalia previously classified in the 1994 kingdom Protozoa. However, it is now apparent that the phylum Microspora has close affinities with the Fungi and should be removed from the subkingdom Archezoa and kingdom Protozoa (see below).

FLAGELLATED ARCHEZOANS: *GIARDIA*, *ENTEROMONAS*, *CHILOMASTIX* AND *RETORTAMONAS*, *DIENTAMOEBA*, *TRICHOMONAS*, AND *PENTATRICHOMONAS*

The flagellated species *Giardia duodenalis*, *Enteromonas hominis*, *Chilomastix mesnili*, and *Retortamonas intestinalis* (parasites of the human intestine) have been traditionally classified with a number of other flagellates within the subphylum or phylum Mastigophora. In this classification, as in the 1994 classification, they have been placed in the phylum Metamodada in what is now the subkingdom Archezoa. Most protozoologists, largely basing their evidence on ribosomal RNA, now regard *Giardia* as very primitive and consider that it represents a very early stage of eukaryote evolution and that in any overall evolutionarily sound scheme it should be placed in some basal, pivotal position. Parallels between *Giardia* and the other genera listed suggest that they should all be grouped together in the same phylum and that *Giardia* and *Enteromonas* should be in one class and *Chilomastix* and *Retortamonas* in another. The 1994 classification separated these flagellates from members of the Trichomonadida, containing *Dientamoeba fragilis* (parasitic in the intestine), two species of *Trichomonas*, *T. vaginalis* and *T. tenax*, and *Pentatrichomonas hominis* (parasitic respectively in the urogenital system, mouth, and intestine). *Dientamoeba* has no flagellum and is permanently amoeboid and was thus once classified with the amoebae, but there is now no doubt that it is a

flagellate and should be classified with *Trichomonas*. Corliss (1994) pointed out that some protozoologists believed that the whole of the phylum Parabasala (now Parabasalia), which contains the Trichomonadida, should be classified with the Archezoa, bringing all these flagellated protozoa of humans closer together; in the present classification this has been done and they are assigned to the phylum Parasbasalia in the subkingdom Archezoa.

AMOEBOFLAGELLATES: *NAEGLERIA*

These freshwater forms are occasional accidental parasites of humans. In previous classifications they have been classified with other amoebae such as *Entamoeba* and *Acanthamoeba*, or with the flagellated protozoa. There is now no doubt that these organisms should be classified with a number of other free-living flagellated protozoa in a separate phylum, Percolozoa, as in the 1994 and present classifications.

AMOEBAE: *ACANTHAMOEBA*, *ENDOLIMAX*, *ENTAMOEBA*, AND *IODAMOEBA*

The arguments for keeping all these amoebae together in one phylum, Rhizopoda in the 1994 classification and Amoebozoa in the present one, are sound. There are also sound arguments for placing *Acanthamoeba* spp. (accidental parasites of humans) in one class, Amoebaea, and the obligate species, *Entamoeba histolytica*, in another, Entamoebidea. The class Amoebaea is equivalent to Lobosea in the 1994 classification. This classification is essentially a traditional one and should be acceptable to parasitologists.

BLOOD AND TISSUE FLAGELLATES: *LEISHMANIA* AND *TRYPANOSOMA*

These important genera include *Trypanosoma brucei gambiense*, *T. b. rhodesiense*, *T. cruzi*, and several species of *Leishmania*. They have long been recognized as comprising a distinct assemblage which has been given several names, ranging from the order Kinetoplastida to the phylum Kinetoplasta. In this classification, they are placed close to their free-living relatives, in the phylum Euglenozoa, which should be satisfactory for both parasitologists and protozoologists.

CILIATED PROTOZOA: *BALANTIDIUM*

The phylum Ciliophora contains ciliated protozoa that all possess distinctive patterns of ciliary distribution and can thus be classified satisfactorily on morphological grounds. *Balantidium coli* is the only ciliate that infects humans and, although in the past its taxonomic position has been uncertain, it is now accepted by most protozoologists that it is correctly classified in the phylum Ciliophora and class Litostomatea. *B. coli* is not an important parasite and is readily recognized, so its classification is of little interest to most parasitologists. However, what is of interest is the fact that the ciliates are now thought to be more closely related to the sporozoans than was previously believed when the protozoa were divided between the four major groups, amoebae, flagellates, sporozoans, and ciliates.

SPOROZOANS

Sporozoa is a traditional term applied to a large group of sexually reproducing, spore-forming protozoa, most of which have recognizably similar morphology at the electron microscope level and similar life cycles. This group originally contained a heterogeneous collection of spore-forming single-celled organisms including, at one time, the microsporidians, here classified in the kingdom Fungi. In the 1970s, a new parasite genus, *Perkinsus*, containing parasites of marine molluscs that were quite different from any of the other sporozoans, was allocated to this group and the phylum Sporozoa was downgraded to a class and the name of the phylum changed to Apicomplexa. The phylum Apicomplexa containing two classes Sporozoea, identical with the taxon Sporozoa established by Leuckart (1879), and Perkinsea containing the genus *Perkinsus* (see Levine et al. 1980). It is now clear that *Perkinsus* spp. do not belong with the sporozoans and should be classified close to, or with, the dinoflagellates (Siddall et al. 1997; Herrán et al. 2000) therefore the taxon Apicomplexa is redundant and should not be used. The traditional sporozoans (that is, all except the members of the class Perkinsea) possess sufficient common morphological features and life cycles, supported by studies at the molecular level, to justify inclusion in a single phylum. In the classification advocated here, Sporozoa replaces the phylum Apicomplexa and many parasitologists will be pleased to see the return of the phylum Sporozoa, which has both priority and common usage. References to Apicomplexa or apicomplexans should now revert to Sporozoa or sporozoans, the original names.

COCCIDIANS: *ISOSPORA*, *SARCOCYSTIS*, AND *TOXOPLASMA*

Members of this group are either parasites that undergo the whole of their life cycle in a single host, typically in the epithelial cells of the gut, or divide a similar cycle between two hosts. Until the early 1970s these parasites were known only from miscellaneous stages in their hosts but since then they have been classified as a tight assemblage on the grounds of morphology, life cycles, and molecular similarities. The species recognized in humans are *Isospora belli*, *Sarcocystis hominis*, *S. suihominis*, and *Toxoplasma gondii*. Although there may be some controversy about their exact identity and relationships, there is no doubt that in this classification they are satisfactorily accommodated in the phylum Sporozoa, Class Coccidea, and Order Eimeriida.

HEMOSPORIDANS: *PLASMODIUM* AND *BABESIA*

These parasites occur in the blood of their vertebrate hosts and have been extensively studied, largely because members of the genus *Plasmodium* cause malaria and members of the genus *Babesia* cause important diseases in cattle. In the 1994 classification, the class Haematozoea contains two orders; Haemosporida, containing members of the genus *Plasmodium*, and Piroplasmida, containing members of the genus *Babesia* which are rare and accidental parasites of humans. There can be little dispute about the classification of the Haemosporida, which is conventional and well accepted. The piroplasms have had a more checkered history, originally being described as sporozoans as long ago as 1889 (Smith and Kilborne 1893), regarded as a suborder by Wenyon (1926), transferred to the amoebae (Honigberg et al. 1964), elevated to the level of a subclass of the class Sporozoa (Levine et al. 1980) and to a class (Cox 1991). In the present classification the redundant class Haematozoa disappears and brings the malaria parasites and piroplasms together as equivalent orders. However, superficial similarities might mask fundamental differences and these may in time be sufficient to justify further separation of the two groups, either as subclasses or classes.

BLASTOCYSTIS

Blastocystis hominis has had a checkered taxonomic history since its discovery nearly 100 years ago and has been classified with the fungi, plants, flagellates, amoebae, and sporozoans. Molecular techniques have now established that it belongs close to the sporozoans and ciliates but in a separate kingdom, Chromista (Silberman et al. 1996; Cavalier-Smith 1998; Arisue et al. 2002). *Blastocystis* is the only parasitic member of this kingdom and is included in this volume for convenience and because of its affinities with other protozoa.

MICROSPORIDIANS: *BRACHIOLA*, *ENCEPHALITOZOON*, *ENTEROCYTOZOON*, *MICROSPORIDIUM*, *NOSEMA*, *PLEISTOPHORA*, *TRACHIPLEISTOPHORA*, AND *VITTAFORMA*

These tissue-inhabiting parasites have also had a checkered history, at one time being classified with the Sporozoa, later in a group with the myxosporidians and in the 1980s and 1994 classifications in a phylum of their own, the Microspora. As these parasites have become increasingly recognized as significant concomitants of HIV infections it is important that they should not be neglected on some classificatory sideline, and they are now thought to be more closely related to fungi than to protozoa (Hirt et al. 1999; Cavalier-Smith 2001). Accordingly they are now classified in the eukaryotic kingdom Fungi but are retained in this volume because they are traditionally considered together with the protozoa. It should be noted that *Pneumocystis carinii* was formerly considered to be a protozoan but has now been formally assigned to the Fungi, and this will probably also be the case with the microsporidians in due course.

INTRODUCTION

There are six species of amebae commonly found in the human gastrointestinal tract. Of these, four belong to the genus *Entamoeba*: *E. histolytica*, *E. hartmanni*, *E. coli*, and the recently redescribed *E. dispar*. The rest represent separate genera: *Endolimax nana* and *Iodamoeba buetschlii*. *Dientamoeba fragilis*, long considered another intestinal amebae has now been shown to be an aberrant trichomonad. Only *E. histolytica* is of medical importance, since it is the causative agent of amebiasis, a potentially fatal disease. Other amebae are of interest mainly because their trophozoites may be difficult to distinguish by light microscopy from trophozoites of *E. histolytica*. *E. dispar*, however, deserves special mention because it is morphologically indistinguishable from *E. histolytica* and accounts for most asymptomatic infections previously assigned to *E. histolytica*.

Because of its clinical importance, most of this chapter is devoted to *E. histolytica*, although reference to the non-invasive *E. dispar* is necessarily included in those sections where differentiation between the two species is relevant. At the end of the chapter, brief consideration is given to the other intestinal amebae of humans, as well as to *E. moshkovskii* (the 'Laredo-type' that can be found in humans), *E. polecki* from pigs, *E. invadens* from reptiles, and *E. chattoni* from monkeys. Additional information may be obtained from Martínez-Palomo (1982, 1993), Espinosa-Cantellano and Martínez-Palomo (2000), Haque et al. (2003), Stanley (2003), and Stauffer and Ravdin (2003).

For the last 70 years, two of the most puzzling aspects of the biology of *E. histolytica* were the unexplained variability of its pathogenic potential and the restriction of human invasive amebiasis to certain geographical areas despite the worldwide distribution of the parasite. The main debate centered on the question of whether there were one or two species of *E. histolytica*. In 1925, the French parasitologist Brumpt proposed that invasive amebiasis is produced by a species of ameba with a worldwide distribution that is biologically distinct but morphologically similar to nonpathogenic amebae (Brumpt 1925). Apart from some isolated studies carried out by Simic, there was nothing to refute or confirm this hypothesis for almost 50 years (Simic 1931). However, in the 1970s, differences in surface properties were found between strains of *E. histolytica* isolated from carriers and those obtained from patients with invasive amebiasis (Martínez-Palomo et al. 1973; Trissl et al. 1977, 1978). Starting in 1978, Sargeaunt and colleagues applied an isoenzyme technique to thousands of isolates of

amebae obtained from several continents (Sargeaunt et al. 1982). This technique is based on the analysis of band patterns obtained after gel electrophoresis of the enzymes hexokinase and phosphoglucomutase. It revealed that invasive amebiasis is produced by strains that have characteristic isoenzyme patterns (zymodemes) distinct from those obtained from amebae harbored by most carriers. Moreover, monoclonal antibodies specifically recognized amebae belonging to pathogenic zymodemes (Strachan et al. 1988; Petri et al. 1990; Tachibana et al. 1990), and molecular probes were able to distinguish between pathogenic and nonpathogenic isoenzyme patterns (Tannich et al. 1991a).

The application of molecular biology to the field finally resolved the problem, and it is now accepted that there are two species: *E. histolytica*, previously known as pathogenic or invasive *E. histolytica*, and *E. dispar* formerly denominated as nonpathogenic or noninvasive *E. histolytica*. For a comprehensive review of the history of the debate, as well as the scientific evidence that supports the conclusion of the distinct natures of *E. histolytica* and *E. dispar*, refer to Spice and Ackers (1992), Diamond and Clark (1993), and Clark and Diamond (1993).

CLASSIFICATION

According to the Committee on Systematics and Evolution of the Society of Protozoologists, the *Entamoeba* are grouped in the family Endamoebidae, order Amoebida, subclass Gymnamoebia, class Lobosea, superclass Rhizopoda, subphylum Sarcodina, phylum Sarcomastigophora (Levine et al. 1980). However, in the 15 years since the last taxonomic scheme for the Protozoa was adopted, new data on the ultrastructure and on the molecular biology of numerous species have rendered it obsolete, and have indicated the necessity for revision of the classification of Protozoa (Cox, 1992; Corliss 1994; see also Classification and introduction to the parasitic protozoa). In Corliss's proposed classification, the amebae are all placed in the phylum Rhizopoda, class Entamoebidea. Within this class, they are classified in the order Endamoebida and the family Endamoebidae. *Dientamoeba* is now considered a flagellate.

The factors currently considered to be useful for differentiation of *Entamoeba* from other amebae have been summarized by Neal (1988) and include intrinsic characteristics such as morphology, type of nuclear division, type of movement, type of physiology, antigenic nature, nature of DNA, variability of isoenzymes, susceptibility to drugs, and extrinsic characteristics such as host specificity, virulence factors, behavior in laboratory hosts, and clinical effects. Riboprinting has also been applied to distinguish different *Entamoeba* species from other intestinal protozoa.

STRUCTURE AND LIFE CYCLE

The trophozoite

The motile form of *E. histolytica*, the trophozoite (Figure 1), is a highly dynamic and pleomorphic cell, the form and motility of which are strongly affected by changes in temperature, pH, osmolarity, and redox potential. Actively motile amebae are elongated in form, with protruding lobopodia and a trailing uroid, whereas resting trophozoites tend to be spherical. The diameter of the cell varies between 10 and 60 μm, not only due to the pleomorphism of the parasite, but also to the feeding conditions: amebae obtained directly from intestinal or liver lesions are generally larger (20–40 μm) than those found in nondysenteric stools or in cultures (10–30 μm). The cell surface has numerous circular openings of diameter 0.2–0.4 μm that correspond to the mouths of micropinocytic vesicles. These openings are absent from the large protruding stomas of macropinocytic channels (2–6 μm in diameter) and from lobopodia. The uroid, when present, appears as a tail formed of irregular folds of the membrane and filiform processes called filopodia. Filopodia can also be found in other regions of the cell

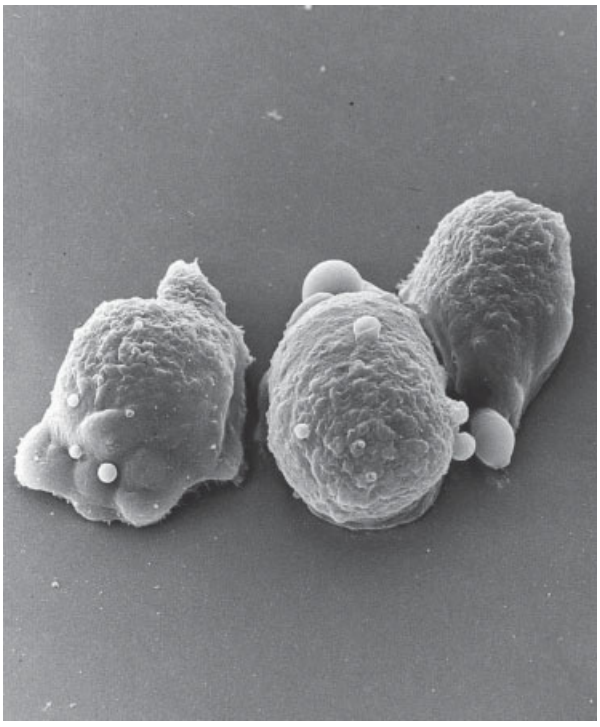

Figure 1 *Scanning electron micrograph of* E. histolytica *cultured trophozoites. Note the rough appearance of the cell surface, except in the regions of pseudopod extension. The parasite on the left shows a trailing uroid opposite to the pseudopod formations and abundant filopodia at the site of membrane attachment. A phagocytic opening of the membrane is clearly evident in the trophozoite located at the center of the micrograph.*

surface and are more frequently observed in amebae in monoxenic cultures or in contact with epithelial tissues (Martínez-Palomo 1982).

THE PLASMA MEMBRANE

The plasma membrane of *E. histolytica* is c. 10 nm thick and is covered by a uniform surface coat composed mainly of glycoproteins (Figure 2). The binding of the lectin concanavalin A to the surface of the trophozoite suggests a high content of sugar residues (i.e. mannose, glucose). In actively motile trophozoites, a thin layer of material is deposited on the substrate, leaving a trail of microexudate with cytochemical properties similar to those of the surface coat (Martínez-Palomo 1982).

Interaction of the trophozoite plasma membrane with specific ligands induces a dramatic redistribution of surface components that accumulate at the uroid and are later released into the medium. This capping of surface molecules, suggested as a mechanism of evasion of the humoral immune response, occurs through a sliding mechanism that involves both actin and myosin and is regulated by calmodulin and a myosin light-chain kinase (Espinosa-Cantellano and Martínez-Palomo 1994).

THE CYTOPLASM

The cytoplasm of *E. histolytica* trophozoites is characterized by the absence of most of the differentiated organelles found in other eukaryotic cells (i.e. mitochondria, Golgi apparatus, rough endoplasmic reticulum, centrioles, and microtubules). Instead, the cytoplasm contains abundant vacuoles of extremely variable size, with diameters 0.5–9.0 μm (Figure 3). Some of these vacuoles have been identified using biochemical and ultrastructural techniques. They include phagocytic vacuoles, macropinocytic and micropinocytic vacuoles, lysosomes, residual bodies, and autophagic vacuoles. Food vacuoles can be observed filled with starch or bacteria in amebae in xenic and monoxenic cultures. Amebae recovered from dysenteric stools usually contain ingested red blood cells; ingestion of red blood cells has traditionally been considered the best evidence of the invasive nature of the parasite. The lysosomes of amebae differ from those of other eukaryotes in that the contained enzymes are bound to the lysosomal membrane rather than being free in the vacuolar compartment (Martínez-Palomo 1986). Our knowledge of this complex vacuolar system is mainly of the vacuoles involved in endocytic processes (Batista et al. 2000). The nature and functions of other vacuoles remain to be determined.

Although no structures resembling classical mitochondria are present in the amebic cytoplasm, the *E. histolytica* genome encodes molecular chaperone cpn60 and pyridine nucleotide transhydrogenase (Yu and Samuelson 1994; Clark and Roger 1995) that are associated with mitochondria in other eukaryotes. Cpn60 has been localized in one or two small (1–2 μm) vacuoles in the cytoplasm of *E. histolytica*. Targeting of cpn60 to this compartment is dependent on short signal peptides that can be replaced with mitochondrial targeting sequences from other protozoa. The crypton or mitosome seems to be a mitochondrial remnant whose function remains unknown.

A lattice of tubules and vesicles superficially resembling smooth endoplasmic reticulum can be found, although very seldom, in the cytoplasm of *E. histolytica* trophozoites. The lattice is made up of extremely thin tubules approximately 20 nm in diameter, forming irregular whorls or parallel arrays. In contrast to the 10 nm thick plasma and vacuolar membranes, the membrane enclosing these tubules is only 6 nm thick (Martínez-Palomo 1982).

Ribosomes appear to be mostly ordered in helical arrays approximately 300 nm long and 40 nm in diameter. In cysts and resting cultured trophozoites, the helices aggregate in large crystalline inclusions that can be several micrometers in length, forming the classic chromatoid body with a hexagonal packing pattern. Whether ribosomes in helices and in chromatoid bodies are functionally mature ribosomes or ribosomal precursors remains to be established.

Despite the striking motility and plasticity of the trophozoite and the important role that the cytoskeleton

Figure 2 *Plasma membrane of a trophozoite of* E. histolytica *seen in a transmission electron micrograph of a cryofixed, cryosubstituted sample. A thick surface coat made of fibrilar material is clearly revealed with these techniques. The surface components here shown are usually lost during ordinary techniques used for fixation and embedding. The section was counterstained with only uranyl acetate and lead citrate.*

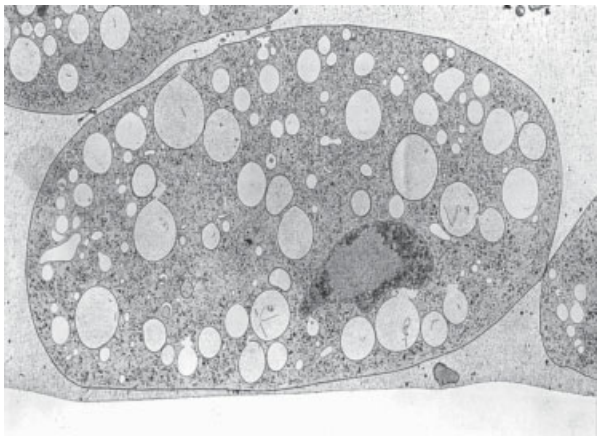

Figure 3 *Transmission electron micrograph of an* E. histolytica *trophozoite in culture. The ultrastructural appearance of the trophozoite is mainly characterized by the lack of mitochondria, a Golgi system, endoplasmic reticulum and cytoplasmic microtubules. Cryofixation and cryosubstitution of the sample provide a better preservation of cytoplasmic components than do standard procedures.*

plays in the invasion process, little was known about the structural organization of the cytoskeleton until recently. Prior to improvements in microscopy, only scarce microfilaments resembling actin (7 nm in diameter) were visible by transmission electron microscopy. The development of cryofixation and cryosubstitution allows much better preservation of biological materials and produces fewer artifacts than chemical fixation. Filaments with the appearance and size of actin have been visualized massed below the plasma membrane and in pseudopodial extensions and phagocytic stoma. Moreover, filaments with the size and appearance of myosin, which had only been observed in immunofluoresence preparations, have been observed with transmission electron microscopy. These studies have confirmed the absence of microtubules in both the cytoplasm and nuclei of nondividing amebae. Microtubules are known to be present in the nuclei of dividing trophozoites (González-Robles and Martínez-Palomo 1992).

Finding cylindrical particles in the cytoplasm of *E. histolytica* generated considerable interest. These particles are found in trophozoites obtained from such diverse sources as colonic exudates from patients with acute amebic colitis, human liver lesions, and axenic and polyxenic cultures. These particles are commonly arranged in rosettes; in thin sections of amebae one or two rosette conglomerates are usually found surrounding a finely granular specialized area of the cytoplasm. Each conglomerate is c. 1 μm in diameter and is composed of 9–30 cylindrical bodies. The bodies vary in size and may be up to 250 nm long and 90 nm wide. They are surrounded by a membrane that is 7 nm thick. They tend to be bullet-shaped, although occasionally they appear rounded at both ends. The morphological similarity of the cylindrical particles to rhabdoviruses, and the cytochemical detection of a dense RNA-containing core in the rosette arrangements of the former have led to speculation of a possible viral nature. There is, however, no conclusive evidence to date about the nature and biological significance of these structures.

THE NUCLEUS

The nucleus of *E. histolytica* is 4–7 μm in diameter. The nuclear membrane is double and is interrupted by numerous nuclear pores c. 65 nm in diameter. The membrane is lined by a thin, uniform layer of granules that gives the nucleus the appearance of a ring in optical section. Chromatin clumps are usually uniform in size and evenly distributed inside the nuclear membrane although in some cells the chromatin appears concentrated on one side as a crescentic mass. The karyosome or endosome is a small, spherical mass c. 0.5 μm in diameter and located in the central part of the nucleus. Intranuclear bodies 0.2–1.0 μm in diameter are frequently observed but their nature and function are unknown. Nuclear division proceeds without dissolution of the nuclear membrane and involves the participation of thick microtubule spindles, but the precise mechanism is unknown. Fluorescence microscopy with the spreading technique has estimated that the number of chromosomes is about 30–50, which agrees with the results obtained from pulse-field gel electrophoresis (Willhoeft and Tannich 2000).

The cyst

Cysts have been studied far less extensively than trophozoites, mainly due to our inability to induce encystation in axenic cultures. Thus, most studies on *Entamoeba* cysts have been carried out on *E. invadens*, a parasite of reptiles that can be made to encyst in culture (reviewed in Eichinger 2001). *E. histolytica* cysts are round or slightly oval hyaline bodies 8–20 μm in diameter. They are surrounded by a refractile wall which is 125–150 nm thick and apparently composed of fibrillar material. This forms a tight mesh and may give rise to several lamellae (Figure 4). In *E. invadens*, the cyst wall has been shown to contain chitin. The plasma membrane frequently has deep invaginations; polyribosomes and vacuoles containing dense fibrogranular material can be observed close to its cytoplasmic face. Food vacuoles tend to disappear as the cyst matures. Staining with iron-hematoxylin makes the cytoplasm appear vacuolated with numerous glycogen deposits that decrease in size and number as the cyst matures. Chromatoid bodies, which are aggregated ribosomes, can be identified inside the cytoplasm as rod-shaped structures with blunt or rounded ends. Iodine stains allow the clear visualization of 1–4 small nuclei.

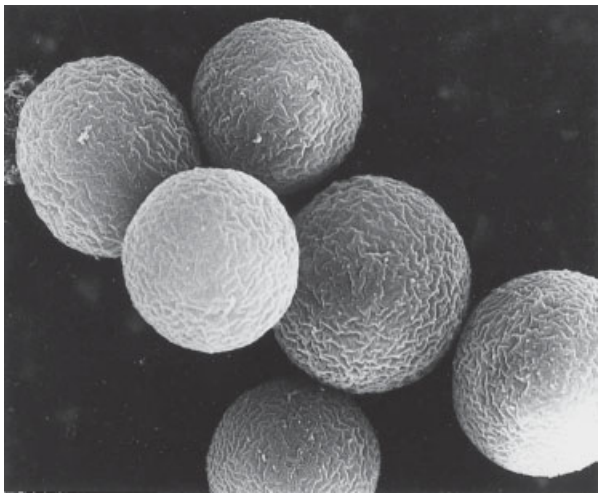

Figure 4 *Scanning electron micrograph of* E. histolytica *cysts recovered from feces of a human carrier. The cyst wall allows the parasite to survive in a relatively hostile environment outside the host.*

The life cycle

Trophozoites dwell in the colon, where they multiply and encyst typically producing four-nucleated cysts. These appear in the formed stools of carriers as round or slightly oval hyaline bodies with a refractive wall. When a cyst is ingested, the cyst wall is dissolved in the upper gastrointestinal tract and the parasite excysts in the terminal ileum, eventually giving rise to eight uninucleated trophozoites. Cysts do not develop within tissues, but the invasive form of the parasite, the trophozoite, can penetrate the intestinal mucosa and disseminate to other organs. Trophozoites are short-lived outside the body and do not survive passage through the upper gastrointestinal tract. In contrast, cysts may remain viable in a humid environment and stay infective for several days.

BIOCHEMISTRY, MOLECULAR BIOLOGY, AND GENETICS

Biochemistry

METABOLISM

The metabolism of the parasite is puzzling since *E. histolytica* is a facultative aerobe with peculiar glycolytic enzymes that are also found in other amitochondriate eukaryotes like *Naegleria*, and in certain bacteria. Glucose and, to a lesser extent, galactose are the main sources of energy. The uptake of glucose occurs via a specific transport system that provides c. 100 times the amount incorporated by endocytosis. This transport system is the rate-limiting step in glucose consumption. Glycogen is the main form of storage.

Glucose-6-phosphate is degraded to pyruvate via the Embden-Meyerhof pathway. A unique aspect of glycolysis in *Entamoeba* is the utilization of inorganic pyrophosphate (PPi), generally considered an end-product of metabolism, as an energy source in several glycolytic reactions. The genes coding for several of these enzymes have been cloned, including pyrophosphate-dependent phosphofructokinase (PPi-PFK) (Huang et al. 1995) and pyruvate phosphate dikinase (PPDK) (Bruchhaus and Tannich 1993; Saavedra-Lira and Pérez-Montfort 1996). In addition, the primary structure of enolase, which catalyses the conversion of 2-phosphoglycerate to phosphoenol pyruvate, has also been reported (Beanan and Bailey 1995).

The end-products of pyruvate degradation depend on the degree of anaerobiosis: under aerobic conditions (5 percent oxygen concentration) acetate, ethanol, and carbon dioxide are formed, whereas in an anaerobic environment, only ethanol and carbon dioxide are produced. The enzymatic activities involved in this process include a pyruvate synthase, aldehyde dehydrogenase (ALDH) and both NAD+-linked and NADP+-linked alcohol dehydrogenase (ADH). The genes encoding an NADP+-dependentADH and ALDH have been cloned (Kumar et al. 1992; Zhang et al. 1994). The presence of a multifunctional NAD+-dependent acetaldehyde/alcohol dehydrogenase, previously found only in anaerobic and facultative anaerobic bacteria, has been reported (Bruchhaus and Tannich 1994; Yang et al. 1994). It has been suggested that during aerobiosis, electrons are transferred from reduced substrates via a succession of carriers (including flavins, ferredoxin, other FeS proteins and ubiquinone) to molecular oxygen, which is reduced to water (Weinbach 1981; Huber et al. 1987; Ellis et al. 1994). The final electron acceptor under anaerobic conditions is not known.

Little is known about nucleic acid, lipid, and protein metabolism (Reeves 1984; McLaughlin and Aley 1985). *E. histolytica* is a purine auxotroph but can apparently synthesize pyrimidines. The parasite seems to be able to synthesize some of its lipids, including cholesterol and isoprenoids. At least three phospholipase activities (A1, A2, and L1) have been detected. Enzymes involved in inositol metabolism have been identified (Lohia et al. 1999), as have some of the early enzymes participating in the biosynthesis of glycosylated proteins (Vargas-Rodríguez et al. 1998; Villagómez-Castro et al. 1998).

E. histolytica is thought to be unique among eukaryotes in that it does not contain glutathione or glutathione-dependent enzymes (Fahey et al. 1984). In other organisms, the primary function of glutathione is to protect against oxygen toxicity. High concentrations of cysteine and other thiols have been identified in *Entamoeba*, which could carry out the functions of glutathione and its dependent enzymes (Fairlamb 1989). In addition, the presence of a disulphide oxidoreductase that binds flavin adenine dinucleotide (FAD) as a

cofactor and can reduce alkyl hydroperoxides and hydrogen peroxide through NADH or NADPH has been suggested as a means of protection against damage by active oxidizing agents (Bruchhaus and Tannich 1995).

PLASMA MEMBRANE AND SURFACE MOLECULES

The biochemical characterization of cellular membranes, and particularly of the plasma membrane, is important for the understanding of host–parasite interactions. Progress in this field has been hampered by the presence of potent proteases, the unavailablity of suitable enzyme markers in the parasite, and the continuous turnover of surface membranes by endocytosis.

Membrane lipids have been studied both in whole extracts of trophozoites and in isolated plasma and internal membrane fractions (Aley et al. 1980). Cholesterol is enriched in the plasma membrane fraction to a molar ratio of 0.87 with phospholipid, a finding consistent with previous reports in other types of cells. Phosphatidylethanolamine predominates over phosphatidylcholine in the plasma membrane, although the latter is the most abundant lipid in internal vesicles. An unusual phospholipid, ceramide aminoethyl phosphonate (CAEP) has been demonstrated in internal vesicles, but is mostly concentrated in the plasma membrane, where it accounts for 35 percent of the total lipid content (Aley et al. 1980). This may have biological importance, as this compound is resistant to hydrolysis and may protect the parasite against the action of its own phospholipase.

Isolated plasma membranes with surface glycoproteins stabilized by concanavalin A treatment yielded a total of 12 glycoproteins ranging from 12 to 200 kDa in molecular weight. These were identified by radiolabeling and autoradiography (Aley et al. 1980). When Percoll density gradients were used to separate these glycoproteins after they had been labeled by lactoperoxidase iodination, 16 bands were identified, nine of which comigrated with ^{125}I-concanavalin A-labeled peptides, a result suggesting they had a glycoprotein nature. The discrepancy in the number of glycoproteins found by these two procedures may be due to the action of amebic proteases activated differently by various lysis conditions. Such proteases have been shown to affect the electrophoretic profile of whole lysates (Espinosa-Cantellano and Martínez-Palomo 1991).

Several surface molecules that mediate adhesion to cells or intestinal mucus are recognized by sera from patients cured of invasive amebiasis. They include:

- a 260 kDa N-acetyl-D-galactosamine inhibitable lectin formed of two subunits, one of 170 kDa and one of 35 kDa (Petri et al. 1989, 1990)
- an N-acetylglucosamine inhibitable lectin of 220 kDa (Rosales-Encina et al. 1987)
- a 112 kDa surface adhesin (Arroyo and Orozco 1987).

Antibodies raised against these proteins partially inhibit adhesion and phagocytosis of target cells in vitro, suggesting that the proteins participate in amebic adherence. The 112 kDa adhesin seems to be composed of two subunits, an adhesin and a protease encoded by adjacent genes (García-Rivera et al. 1999). In addition, *E. histolytica* expresses two lipophosphoglycan (LPG)-like molecules that may also participate in adhesion (Isibasi et al. 1982; Moody-Haupt et al. 2000). Conflicting reports on whether *E. dispar* synthesizes LPG have been published, one group having identified only one of the two molecules (Moody et al. 1998), while the other did not find any LPG even after using different methods of extraction in several isolates (Bhattacharya et al. 2000). Other surface antigens identified by sera from patients include peptides of 30, 96, and 125 kDa, a serine rich *E. histolytica* protein and a lipopeptidophosphoglycan (reviewed in Espinosa-Cantellano and Martínez-Palomo 1991).

Among the enzymes identified in the plasma membrane of *E. histolytica* are Ca2+-adenosine triphosphatase (ATPase), phospholipase A, neuraminidase and a metallocollagenase thought to play an important role during parasite invasion (reviewed in Espinosa-Cantellano and Martínez-Palomo 1991). Cysteine proteases are the most abundant proteases and have also been implicated in the pathogenicity of *E. histolytica* trophozoites (Keene et al. 1990). Four major cysteine proteases have been reported:

1. a 56 kDa cysteine protease (Keene et al. 1986)
2. a 26–29 kDa histolysin (Luaces and Barret 1988)
3. a 22–27 kDa amebapain (Scholze et al. 1992)
4. a 16 kDa cathepsin B-like protease (Lushbaugh et al. 1985).

Three different cysteine protease genes have been described. Protein sequences of purified enzymes suggest that one gene encodes amebapain and a second one histolysin. The amebic cysteine proteases are secreted enzymes and are, therefore, mainly located in the internal vesicles but some have been identified on the surface of the trophozoite. The identity of the higher molecular mass proteases was uncertain, but recent reports have started to answer this question. Cysteine proteases of 35 and 48 kDa were identified as products of EhCP2 and EhCP1, respectively, after purification and partial N-terminal sequencing (Hellberg et al. 2000). In addition, a novel 60 kDa cysteine protease, probably involved in erythrophagocytosis (Spinella et al. 1999) and a 50 kDa protease forming a tight complex with a 75 kDa adhesin (García-Rivera et al. 1999) have been reported in the parasite.

LYTIC FACTORS

E. histolytica derives its name from its ability to lyse virtually every tissue in the human body and in the

Figure 5 *Scanning electron micrograph of guinea pig cecal mucosa. A microulceration has been experimentally produced by trophozoites of* E. histolytica. *This lesion exemplifies the earliest stage in the development of intestinal invasive amebiasis.*

bodies of experimental animals (Figure 5). Lysis of target cells involves contact-dependent as well as contact-independent mechanisms. Initial attachment of the trophozoite occurs via the amebic adhesins described above. It has been suggested that, once attached, the parasite releases an active peptide, the amebapore, which is capable of inserting ion channels into liposomes and which possesses cytolytic and bactericidal activities (Leippe et al. 1994; Bruhn and Leippe 1999). *E. dispar* also possess channel-forming proteins that have been called disparpores, but seem to have different activities (Nickel et al. 1999). During the process of tissue invasion, degradation of extracellular matrix components (ECM) possibly involves specific receptors. A receptor common for fibronectin and laminin has been identified in trophozoites of *E. histolytica* (Talamás-Rohana et al. 1994). The actual degradation of ECM occurs as a result of action by the collagenase and secreted cysteine proteases that have been shown to be active against a wide variety of ECM proteins, including collagen, fibronectin, laminin, and some proteoglycans. Interestingly, the expression of cysteine protease genes has been found to be 10–100-fold higher in pathogenic *E. histolytica* than in nonpathogenic *E. dispar* strains (Tannich et al. 1991b).

Molecular biology and genetics

The total DNA content is 0.5 pg per cell, all of which is concentrated in the nucleus; there are no DNA-containing organelles (Byers 1986). Molecular analysis indicates that there is a complex karyotype with 31–35 chromosomal bands, ranging in size from 0.3 to 2.2 megabases and 14 linkage groups each with a ploidy of at least 4 (Willhoeft and Tannich 2000).

In most other unicellular eukaryotes, rDNA is present intrachromosomally. In contrast, rDNA in *Entamoeba* seems to exist exclusively as extrachromosomal circular molecules (Bhattacharya et al. 1989; Huber et al. 1989). This peculiar characteristic is also shared by *Naegleria*.

Various circular DNA molecules that are not circular rDNA have been detected by Southern blot analysis (Dhar et al. 1995). The fact that such circular DNA exists in the nucleus is supported by the identification (through hybridization with various circular DNA clones) of protein-coding regions in exonuclease-resistant DNA (Lioutas et al. 1995). The origin and function of these circular DNA elements remains to be established but their presence could explain, at least partially, the large variations in number and size of the karyotype of the parasite. The first *E. histolytica* gene was cloned in 1987 (Edman et al. 1987; Huber et al. 1987) and since then, numerous genes have been identified, their sequences analyzed, and their products characterized. An *E. histolytica* Genome Project has rapidly advanced. The genome is highly repetitive and introns are found in 15 percent of genes encoding proteins (Mann 2002).

Despite impressive advances in our understanding of the molecular biology of *Entamoeba*, many questions in the field are far from being resolved. *E. histolytica* has been successfully transfected and this allows studies on gene regulation, on the biological significance of various molecules for the survival of the parasite and on the mechanisms by which it produces disease (Nickel and Tannich 1994; Purdy et al. 1994).

CLINICAL ASPECTS

The term ‘amebiasis’ includes all cases of human infection with *E. histolytica*, but only a proportion of cyst-releasing individuals have symptoms due to the penetration of the parasite into the tissues, a condition known as ‘invasive amebiasis.’ The large group of infected, asymptomatic individuals, previously described as having ‘luminal amebiasis,’ is now thought to be composed mainly of *E. dispar* carriers.

Invasive amebiasis is a potentially fatal condition and there is a relatively high mortality among patients with severe forms of the disease. On a global scale, it ranks second after malaria as a cause of death among people with parasitic infections produced by protozoa (Walsh 1984).

CLINICAL MANIFESTATIONS

An epidemic of amebic dysentery that occurred in Chicago in 1933 provided an opportunity for studying the incubation period of the disease. Contamination of the water supply of two large hotels in the area was responsible for this outbreak, which resulted in around 1 400 cases of amebic dysentery. Although the complete history could not be obtained from all patients, reliable data were available from 391 cases. In these, the incubation periods ranged from 1 to 19 weeks, divided as follows: less than 1 week (6.7 percent), 1–4 weeks (59 percent), 4–8 weeks (24.7 percent), 9–13 weeks (7.4 percent), and more than 13 weeks (2.2 percent). Severe infections tended to have a shorter incubation period, most of them being reported within 1–6 weeks after initial exposure (US Treasury Department 1936).

Depending on the affected organ, the clinical manifestations of amebiasis are intestinal or extraintestinal. Both localizations can occur at the same time, but they are usually manifested separately.

Intestinal amebiasis

There are four clinical forms of invasive intestinal amebiasis, all of which are generally acute:

1. dysentery or bloody diarrhea
2. fulminating colitis
3. amebic appendicitis
4. ameboma of the colon.

The first of these is considered to be relatively benign, but the other three are severe forms of the disease and require prompt medical attention.

AMEBIC DYSENTERY

Dysenteric and diarrheic syndromes account for 90 percent of the cases of invasive intestinal amebiasis. Their various clinical manifestations depend on where the lesions are located within the rectosigmoid or higher regions of the colon. In people with this form of the disease, rectosigmoidoscopy may reveal superficial ulcerations extending over limited areas of the terminal portion of the large intestine. Patients with dysentery have an average of 3–5 mucosanguineous evacuations per day with moderate colic pain preceding discharge, they also have rectal tenesmus. In patients with bloody diarrhea, evacuations are also few, but the stools are composed of liquid fecal material stained with blood and, although there is moderate colic pain, there is no rectal tenesmus. Fever and systemic manifestations are generally absent. These syndromes constitute classic ambulatory dysentery and can easily be distinguished from diseases of bacterial origin. The clinical course is moderate and symptoms disappear rapidly with treatment; spontaneous remissions are occasionally observed after several days (Sepúlveda and Treviño-García Manzo 1986; Martínez-Palomo and Ruíz-Palacios 1990).

FULMINATING AMEBIC COLITIS

In contrast to the dysenteric syndrome, fulminating amebic colitis is an extremely severe, rapidly evolving clinical condition with necrotic ulcerous lesions extending over large areas, even the entire colon. These can affect all layers of the intestinal wall. Evacuations, preceded by intense colic pain, are frequent (20 or more in 24 h) and consist of fecal material mixed with blood or occasionally blood alone. Rectal tenesmus tends to be constant and acute. Systemic manifestations include abdominal discomfort, anorexia, and nausea. High fever (39–40°C) is usually present, accompanied by a weak, rapid pulse and low blood pressure. The patient suffers from dehydration and prostration, and may even develop shock. Peritonitis is a common complication due to the perforation of the intestinal wall (Sepúlveda and Treviño-García Manzo 1986; Martínez-Palomo and Ruíz-Palacios 1990).

AMEBIC APPENDICITIS

The symptoms of this condition are similar to those of bacterial appendicitis: acute pain and rigidity in the lower right quadrant of the abdomen, fever, tachycardia, and nausea. In more than two-thirds of cases of amebic appendicitis, patients have ulcerous lesions of the cecum. In these cases, diarrhea, often bloody, is also present (Sepúlveda and Treviño-García Manzo 1986; Martínez-Palomo and Ruíz-Palacios 1990).

AMEBOMA

Amebomas are pseudotumoral lesions, whose formation is associated with necrosis, inflammation and edema of the mucosa, and submucosa of the colon. Amebomas always co-exist with amebic ulcerations. These are generally single, but occasionally multiple, masses, usually found in the vertical segments of the large intestine: the cecum, the rectosigmoid region, and the hepatic and splenic angles of the colon. The condition is usually acute with dysentery or bloody diarrhea, abdominal pain, and a palpable mass in the corresponding area of the abdomen. If the lesion is located in the rectosigmoid region, it can be identified by endoscopy (Sepúlveda and Treviño-García Manzo 1986; Martínez-Palomo and Ruíz-Palacios 1990).

Extraintestinal amebiasis

E. histolytica can infect almost every organ of the body, including the liver, brain, lung, and skin. By far the most frequent form of extra-intestinal amebiasis is the amebic liver abscess which, due to its great clinical and epidemiological importance, is the most extensively discussed here.

Thoracic complications of amebiasis, including pleuropulmonary, pericardial, and mediastinal manifestations, are secondary to liver abscess. Involvement of the central nervous system is rare and lesions are single or multiple small areas of softening in the left cerebral hemisphere. Cutaneous amebiasis is usually a complication of intestinal amebiasis with dysentery. It may occur in the perianal region, or it may appear in the skin surrounding a fistula in cases of liver abscesses that involve the abdominal wall.

AMEBIC LIVER ABSCESS

This condition results from the migration of *E. histolytica* trophozoites from the colon to the liver via the portal circulation. The time lapse between penetration of the mucosa of the large intestine and damage to the hepatic parenchyma is unknown. It has been observed clinically and confirmed in a large series of autopsies that amebic colitis is found in only one-third of cases of hepatic abscess. Amebic liver abscesses have been reported in patients of all ages, but predominate in adults between 20–60 years. It has a marked preference for the right lobe of the liver and it is at least three times more frequent in males than in females. Interestingly, it is 10 times more common in adults than in children (Sepúlveda and Treviño-García Manzo, 1986).

The signs and symptoms of amebic hepatic abscess vary but, in general, the onset is abrupt with pain in the right hypochondrium radiating towards the right shoulder and scapular area. The pain usually increases with deep breathing, coughing, and while stepping on the right foot during walking. When the abscess is localized to the right lobe, symptoms include irritative cough, sometimes productive, and a pleuritic type of pain. Abscesses in the upper left lobe can cause epigastric, sometimes dyspneic pain, at times spreading to the base of the neck and to one or both shoulders. A sharp increase in pain centered in the precordial region strongly suggests that the abscess has penetrated into the pericardial space. This complication is nearly always fatal due to cardiac tamponade. Localization of the abscess in the vicinity of the diaphragm can lead to perforation of the pleura, causing pleurisy or empyema. If the bronchi become involved, pus may be vomited leading to clinical improvement. If the lung is involved, there may be pulmonary consolidation and abscess formation. When located in the inferior part of the liver, the abscess can penetrate into the peritoneal cavity and into neighboring organs (Sepúlveda 1970).

Fever between 38 and 40°C is found in all patients with amebic liver abscess. The patient commonly has chills and profuse sweating in the afternoon and at night. Other symptoms include anorexia, nausea, vomiting, and, of course, diarrhea (with or without blood), and dysentery. On physical examination, the cardinal sign of amebic liver abscess is painful hepatomegaly. Digital pressure and fist percussion often produce intense pain in the liver region. On palpation, the liver is soft and smooth, in contrast to the rough hard irregular character of the liver in patients with cirrhosis and hepatocarcinoma (Sepúlveda 1970). Jaundice is present in 8 percent of the patients that respond well to treatment. When jaundice is severe, multiple abscesses should be suspected (Figure 6). Ascites and hepatic coma occur rarely, but prognosis is poor in these patients.

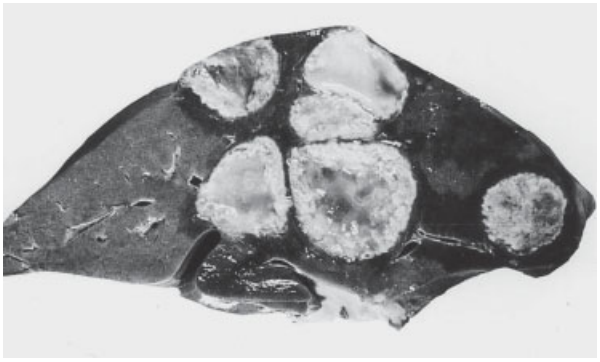

Figure 6 *Macroscopic appearance of amebic liver abscesses. When viewed microscopically, these lesions represent areas of liquefactive necrosis, rather than true abscesses.*

IMMUNOLOGY

Humoral immune response

The time between infection with *E. histolytica* and the appearance of local antibody responses remains unknown. Coproantibodies have been found by indirect hemagglutination assay (IHA) in c. 80 percent of patients with amebic dysentery, compared to 2 percent of healthy controls and 4 percent of patients with nonamebic intestinal parasitic infections; this figure was obtained at the time when patients came in for treatment, but 3 weeks later it fell to 55 percent. This coincided with an increase in serum antibodies suggesting that the humoral immune reaction in people with invasive intestinal amebiasis is initiated by a short and transient local secretory response, followed by an increase in systemic antibodies (reviewed in Pérez-Montfort and Kretschmer 1990). Immunoglobulin (Ig)A-type anti-*E. histolytica* antibodies have also been found in human milk, colostrum, and saliva, and in the bile of intracecally immunized rats. The protective role of secretory IgA (and IgE) in amebiasis has not been established. In fact, *E. histolytica* trophozoites have been shown to degrade secretory IgA (Kelsall and Ravdin 1993).

Circulating antibodies to *E. histolytica* can be detected as early as 1 week after the onset of symptoms in humans and experimental animals. All immunoglobulin classes are involved, but there seems to be a predominance of IgG. In contrast to findings in animals, the

levels of circulating antibodies in humans do not necessarily correlate with the severity of the disease. High titers of antibodies tend to appear early in the disease and to persist after invasive amebiasis is cured and in patients whose subclinical amebic infection is controlled (Knobloch and Mannweiler 1983). Antibody levels fall in different people at different rates following treatment. The detection of antibody in a patient depends on the sensitivity of the test used. Thus, if antibodies are measured by the sensitive techniques of IHA or by enzyme-linked immunosorbent assay (ELISA), antibodies can be detected more than 3 years after an invasive amebic episode in the absence of any recurrent infection (reviewed in Kretschmer 1986).

Complement may also be involved in limiting amebiasis, a role supported by the observation that experimental animals decomplemented with cobra venom factor are significantly more susceptible to development of amebic liver abscess than are normal animals. Also, the addition of cobra venom factor to normal human serum decreases the lysis of complement sensitive strains (Reed and Gigli 1990). Moreover, amebae are capable of activating complement through the classical and alternative pathways, even in the absence of antibody (Calderón and Schreiber 1985). This activation is lethal in vitro to the non-invasive *E. dispar*, and to *E. histolytica* strains that have been axenized and have partially lost their virulence. However, fresh isolates from patients with colitis or amebic liver abscesses are resistant to complement-mediated lysis (Reed et al. 1983) and repetitive treatment with human serum may induce complement resistance of axenic *E. histolytica* in culture (Calderón and Tovar 1986) suggesting that some amebae have developed a mechanism not yet understood for evasion of complement lysis. These observations may explain the conflicting reports of complement levels in humans and in experimental animals with invasive amebiasis: some suggest decreased levels of complement whereas others suggest elevated levels.

The deleterious effects of antiamebic antibodies on in vitro cultured trophozoites have been studied extensively. Immune sera can inhibit both erythrophagocytosis by *E. histolytica* and the cytotoxic effect of amebae on cells of cultured lines. At high concentrations, immune serum produces rapid lysis of trophozoites (reviewed in Kretschmer 1986). In apparent contrast to these observations, amebae may survive exposure to antibody in some circumstances. Incubation of amebae with immune serum induces the rapid redistribution of surface-bound antigens to the uroid of the cell and the caps thus formed can be either released or endocytosed. This process is both temperature and pH dependent, occurs through a sliding mechanism that involves both actin and myosin, and is regulated by calmodulin and a myosin light-chain kinase (Espinosa-Cantellano and Martínez-Palomo 1994). The parasite, which has thus shed the antibody–antigen complexes, apparently emerges undamaged and free of potentially harmful antibodies.

Taken together, these observations suggest that although a rapid humoral immune response is mounted by the host upon invasion by *E. histolytica*, the parasite has developed efficient evasion mechanisms that include resistance to complement and a mechanism for capping and shedding surface antigens. It is, therefore, considered that humoral antibodies are not protective against *E. histolytica*, a conclusion further supported by the observation of high rates of reinfection in persons with elevated antibody titers and by the detection of high levels of antibodies in patients with symptomatic amebiasis.

Cellular immune response

Even though the basic components of a local cellular immune response, such as mononuclear phagocytes and lymphocytes, are regularly present in early intestinal amebic lesions, their role in the establishment or prevention of invasive infection is not well understood. Evidence of systemic cell-mediated immunity has been confirmed in vivo through delayed hypersensitivity skin reactions, and in vitro through lymphokine (macrophage inhibition factor (MIF)), blastogenic response, leukocyte adherence inhibition, and lymphocytotoxic assays. Many patients, however, fail to react to delayed skin tests with amebic antigens during the early stages of the disease, apparently due to a state of specific unresponsiveness. Such unresponsiveness has been detected by in vitro assays, which show a transient failure to produce MIF, and by a reduction of lymphocyte cytotoxicity in patients in early stages of untreated hepatic amebiasis (reviewed in Kretschmer 1986). Thus tissue invasion by *E. histolytica* must be preceded by and be associated with some degree of T-cell suppression as a result of either selection or induction of suppressor T cells. Supporting the selective mechanism is the observation of increased susceptibility to invasive amebiasis of patients and experimental animals immunosuppressed by mechanisms mediated by suppressor T cells. The coincidence of malnutrition and amebic liver abscess in over 90 percent of clinical and autopsy cases and the significantly increased HLA-DR3 antigen levels found in Mexican patients with amebic liver abscess also suggest that T-cell mediated suppression is a factor in invasive amebiasis. The inductive proposal, on the other hand, is based on the observation that cell-free extracts of the parasite can exhaust, and thus suppress, the cellular immune response of the host (Kretschmer 1986).

The existence of an early transient anergy state does not necessarily preclude a protective role for cell-mediated immunity against invasive amebiasis. In fact, a state of cell-mediated immunity may be responsible for the rarity of recurrences of amebic liver abscesses in humans: 0.04 percent recurrences versus 0.2 percent

amebic liver abscess per initial infection per year calculated in Mexico City (Kretschmer 1986), although a study of 2 013 cases of amebic liver abscess in Vietnam did not support the concept of a long-lasting immunity against recurrent liver abscess (Blesmann et al. 2002).

The existence of a partial cellular, rather than humoral, immunity against extraintestinal amebiasis is based on the following findings:

- immunization studies and studies of the effect of immunosuppression of experimental animals on infection
- the results of a few studies of passive transfer of immunity with cells
- the cytolytic effect of activated lymphocytes and macrophages (irrespective of the presence of antibodies or complement) against *E. histolytica*.

This conclusion is further supported by studies on severe combined immunodeficient (SCID) mice, in which 100 percent developed liver abscesses when challenged intrahepatically with *E. histolytica* trophozoites (Cieslak et al. 1992). The actual defense strategy seems to depend heavily on macrophages; depressing macrophage function with silica or antimacrophage serum increases the development of experimental amebiasis, whereas enhancing macrophage function with bacille Calmette-Guérin (BCG) decreases such development. Moreover, congenitally athymic nu/nu mice (which are devoid of T lymphocytes) develop amebic liver abscesses or intestinal amebic disease only after macrophage blockade with silica. *E. histolytica* may possess mechanisms to evade or modify the action of macrophages. The parasite has been found to release a small molecular weight factor that can inhibit the locomotion of monocytes, but not of polymorphonuclear cells (reviewed in Kretschmer 1986).

PATHOLOGY

A detailed description of the pathological changes in amebiasis is beyond the objectives of this chapter, but a brief summary of the main characteristics of intestinal and hepatic lesions is given. For a comprehensive review of the pathology of the disease, refer to Pérez-Tamayo (1986).

Invasion of the colonic and cecal mucosa begins in the interglandular epithelium. Cell infiltration around invading amebae leads to rapid lysis of inflammatory cells and tissue necrosis (Figure 7); thus, acute inflammatory cells are seldom found in biopsy samples or in scrapings of rectal mucosal lesions. Ulcerations may deepen and progress under the mucosa to form typical flask ulcers. These extend into the submucosa producing abundant microhemorrhages, the presence of which explains the finding of hematophagous amebae in stool specimens and in rectal scrapings. Such ameba are the best indication of the amebic nature of a case of dysentery or bloody diarrhea. The ulcers are initially superficial, with hyperemic borders, a necrotic base, and normal mucosa between the sites of invasion. Further progression causes the loss of mucosa and submucosa; the lesion can extend into the muscle layers and eventually cause rupture of the serosa.

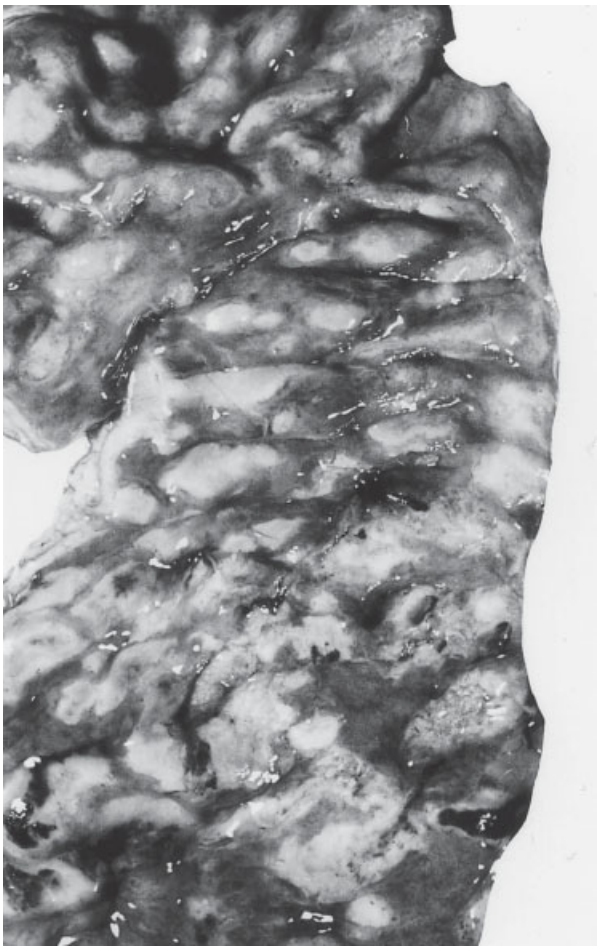

Figure 7 *Surface view of the mucosa of the colon in a fatal case of amebic colitis. Large and confluent ulcerations have destroyed most of the mucosal layers of the large intestine.*

Complications of intestinal amebiasis include perforation, direct extension to the skin and hematogenous dissemination, mainly to the liver. The presence and extent of liver involvement bears no relationship to the degree of intestinal amebiasis, and these conditions do not necessarily coincide. The early stages of hepatic amebic invasion have not been studied in humans. In experimental animals, inoculation of *E. histolytica* trophozoites into the portal vein produces multiple foci of infection in the liver with neutrophil accumulation around parasites, followed by focal necrosis and granulomatous infiltration. As the lesions grow in size, the granulomas gradually become necrotic and coalesce, necrotic tissue occupying progressively larger portions of the liver. Hepatocytes close to the early lesions degenerate and become necrotic, but direct contact of hepatocytes

with amebae is rarely observed. The lesion can eventually consist of large areas of liquefied necrotic material surrounded by a thin capsule of fibrous appearance (Tsutsumi et al. 1984).

DIAGNOSIS

Traditionally, the diagnosis of invasive intestinal amebiasis has been based on the microscopic identification of *E. histolytica* trophozoites in rectal smears or recently evacuated stools and on the results of rectosigmoidoscopy. However, the microscopic detection of amebae has several drawbacks. The procedure is tedious and time consuming; it requires a skilled technician; the sensitivity is relatively low; several samples must be taken to detect cyst passers, and fresh samples are needed for the detection of trophozoites. Trophozoites are most likely to be found in material obtained during rectosigmoidoscopy such as the bloody mucus and in the yellowish exudate covering the mucosal ulcerations. The finding of motile trophozoites containing ingested red blood cells confirms the diagnosis of amebic infection in patients with the clinical gastrointestinal symptoms. Problems arise when cysts alone are identified in stools of healthy or diarrheic individuals, as the cysts may be those of the nonpathogenic *E. dispar*, which are morphologically indistinguishable from cysts of the pathogenic *E. histolytica* (Martínez-Palomo 1993).

The standard for the differentiation of *E. histolytica* from *E. dispar* was, until recently, the determination of their isoenzyme pattern by gel electrophoresis. This procedure is expensive, slow, and requires the cultivation of amebae from feces, which is not routinely applicable. New diagnostic methods are now based on the detection in stool of *E. histolytica*-specific antigen or DNA and by the presence of antiamebic antibodies in serum (reviewed in Tanyuksel and Petri 2003).

Monoclonal antibodies found by ELISA and immunofluorescence assays of fecal samples have been tested. Although the ELISA was reported to have high sensitivity and specificity in a study of 701 samples, it could not discriminate between pathogenic *E. histolytica* and nonpathogenic *E. dispar* (del Muro et al. 1987). The immunofluoresence test, on the other hand, proved to be much faster than the test based on isoenzyme determination, but still required cultivation of the organism, and detected only the motile form of the parasite (Strachan et al. 1988). An ELISA based on monoclonal antibodies directed against cross-reactive and specific *E. histolytica* epitopes of the amebic galactose adhesin is now available commercially. The authors reported that the test gives 93 percent specificity and 96 percent sensitivity in the detection of infection with pathogenic *E. histolytica* (Haque et al. 1994).

Molecular probes provide another approach for the detection of the parasite in stools. A study with a specific probe of 123 stool samples from patients in Mexico City revealed a 93 percent specificity and 100 percent sensitivity for detection of amebae in stools, although it could not distinguish between amebae with pathogenic and nonpathogenic isoenzyme patterns (Samuelson et al. 1989). A study carried out in the south-eastern state of Chiapas in Mexico, using polymerase chain reaction (PCR) to amplify specific pathogenic and nonpathogenic samples resulted in 98 percent specificity and 96 percent sensitivity for the identification of *E. histolytica* in stools of 201 randomly selected individuals (Acuña-Soto et al. 1993).

A comparison of the ELISA and PCR methods to differentiate *E. histolytica* from *E. dispar* in stool samples revealed that the ELISA test is less sensitive (Gonin and Trudel 2003). The specificity of PCR was confirmed in a study of a large number of isolates from both species obtained in three different continents (Zaki et al. 2002). In addition, a closed-tube, real-time PCR assay has given improved results over traditional PCR methods (Blesmann et al. 2002).

The diagnosis of invasive intestinal amebiasis may be confirmed by endoscopy. In patients with benign dysentery, examination by rectosigmoidoscopy reveals small superficial ulcerations of a linear or oval shape, covered by a yellowish exudate and surrounded by a normal or hyperemic mucosa. In patients with fulminating colitis, the ulcers are large and tend to be confluent, often with a necrotic appearance. The intervening mucosa shows intense inflammation and signs of hemorrhage. Endoscopy should be carried out with great care in these cases, as there is a risk of intestinal perforation. If an ameboma is situated in the terminal portion of the colon, it can be visualized by rectosigmoidoscopy. If it is located elsewhere, it is necessary to use colonoscopy or radiography and a barium enema to identify the pseudotumoral mass, which is often surrounded by ulcerations (Sepúlveda 1970).

The diagnosis of amebic liver abscess is sometimes difficult. In endemic areas or when there is a history of travel to such places, amebic abscess should always be suspected in patients with spiking fever, weight loss, and abdominal pain in the upper right quadrant or epigastrium, as well as in patients with tenderness in the liver area. The presence of leukocytosis, a high level of alkaline phosphatase and an elevated right diaphragm (visible in a chest X-ray) suggests the presence of an hepatic abscess. The diagnosis is confirmed by ultrasonography or by computerized axial tomography (CAT) scans. The latter is the most precise method for identifying hepatic abscesses, particularly when they are small, and it is of great value in the differential diagnosis of other focal lesions of the liver (Sepúlveda and Treviño-García Manzo 1986).

Serological tests for antiamebic antibodies are positive in c. 75 percent of patients with invasive colonic amebiasis and in more than 90 percent of patients with amebic liver abscesses. Circulating antibodies have been

detected by virtually all known serologic tests, including tests based on immunofluorescent antibodies (IFA), IHA, radioimmunoassay (RIA), counterimmunoelectrophoresis (CIE), and ELISA. The latter is the most sensitive (it gives no false negatives in cases of amebic liver abscess), it is reasonably specific (3.6 percent false positives in controls living in endemic areas), and remains positive longest (more than 3 years in the absence of recurrent infection) (reviewed in Kretschmer 1986). The IFA test also deserves special mention because it is much simpler than all other tests, and when carried out in conjunction with IHA gives a 100 percent positivity in cases of amebic liver abscess. The Center for Disease Control in Atlanta, Georgia, has chosen the IHA as its standard serologic reference test for amebiasis. Titers below 1:256 are considered nonspecific. Because of its relative simplicity and efficiency, the CIE is particularly well suited for epidemiologic surveys.

Although serological techniques are useful in the diagnosis of invasive intestinal amebiasis and amebic liver abscess and as a tool for epidemiological studies of the disease, they do not aid in the diagnosis of simple intestinal infection. In endemic areas, the high prevalence of antiamebic antibodies in the general population reduces the usefulness of serologic tests for diagnosis and other tests must be performed before establishing the diagnosis of invasive amebiasis. Attempts have been made to discriminate serologically between present and past invasive amebiasis, using antibodies to specific antigens in sera of:

- patients with active or cured amebic liver abscesses
- individuals who are asymptomatic cyst carriers (Ximénez et al. 1993).

An antigen-detection ELISA in serum has proved to be useful (Haque et al. 2003).

EPIDEMIOLOGY AND CONTROL

Infection by *E. histolytica* is ubiquitous, but the highest incidence is usually found in communities with poor socioeconomic conditions and inadequate sanitation. In such communities, the infection is typically endemic. According to the World Health Organization, approximately 500 million people (not including those in the People's Republic of China) are infected with a 10 percent annual morbidity index (Walsh and Martínez-Palomo 1986), and up to 110 000 deaths annually can be attributed to complications of the disease (WHO, 1985). However, the actual frequency of amebiasis due to *E. histolytica* has been difficult to establish because there is a tendency to overestimate it in endemic areas, where cases of dysentery or bloody diarrhea are often misdiagnosed as amebiasis. In nonendemic areas with a low incidence of the disease, there is a tendency to overlook the presence of *E. histolytica* in stools.

In areas with high levels of poverty, illiteracy, and overcrowding, plus inadequate and contaminated water supplies and poor sanitation, direct fecal–oral transmission occurs frequently and the endemic character of the disease is maintained. Although difficult to implement, programs for the control of the disease require the improvement of environmental sanitation, health education, and early detection and treatment of infected people.

EPIDEMIOLOGY

Serological surveys

Antiamebic antibodies are relatively long-lasting in the serum of recovered patients and although antibodies cannot be used to discriminate between persons with recent and past infection, or between those infected with *E. histolytica* and *E. dispar*, detection of antibodies in the population has proved to be a valuable tool in epidemiological prevalence studies. A national seroepidemiological survey was undertaken in all 32 states of Mexico, with a probability-based sampling of almost 68 000 individuals who were representative of the population in age, socioeconomic status, and urban or rural origin. Antibodies to *E. histolytica* were detected by IHA assays in 8.41 percent of the population, ranging from 9.80 percent in the South Pacific region to 6.26 percent in the north-eastern parts, with a higher prevalence in rural (9.89 percent) than in urban (7.93 percent) areas. Frequency of presence of antibodies increased during the first decade of life, reaching the highest prevalence in children aged between 5–9 years. Antibody was detected more frequently in women (9.34 percent) than in men (7.09 percent). There was a clear correlation between high seroprevalence, low socioeconomic and educational levels, and inadequate housing conditions, although positive samples were found in all groups (Caballero-Salcedo et al. 1994).

A previous national serological survey of nearly 20 000 serum samples from 46 Mexican urban regions detected an average frequency of amebic seropositivity of 5.95 percent (Gutiérrez et al. 1976). The differences between these studies do not necessarily reflect an increase in seroprevalence in the Mexican population, but may be due to differences in the populations studied (the latter including only urban areas) and the methodology applied (IHA versus CIE).

Human susceptibility

The main reservoir of *E. histolytica* is human, although morphologically similar amebae may be found in primates, dogs, and cats. The parasite has been transmitted to various mammalian species, but it is doubtful that species other than humans serve as significant reservoirs of the parasite. Human susceptibility to infection

appears to be widespread, but most individuals harboring the parasite do not develop disease. It is now known that most of these asymptomatic carriers are infected with the noninvasive *E. dispar* although *E. histolytica* has been positively identified in some asymptomatic persons. In a semi-rural area south of Durban, South Africa, 1 percent of apparently healthy individuals were carriers of pathogenic *E. histolytica* and a 1-year follow-up revealed that 90 percent of these carriers remained asymptomatic and underwent spontaneous cure, the remaining 10 percent developed amebic colitis (Ghadirian and Jackson 1987). The factors involved in the development of disease are unknown, but probably include host as well as parasite characteristics.

Frequent luminal amebic infections have been reported in male homosexual populations in North America, northern Europe, and Japan. The spread in this group is associated with specific sexual practices; prevalence rates are as high as 32 percent and most reported cases are asymptomatic or present diffuse symptoms. *E. dispar* has been most frequently identified, except in Japan, where pathogenic *E. histolytica* is not uncommon (Takeuchi et al. 1990).

Incidence of invasive amebiasis

There are a few epidemiological reports of invasive intestinal amebiasis that are accompanied by microscopic identification of *E. histolytica* trophozoites and rectosigmoidoscopy studies showing intestinal ulcerative lesions; these reports provide divergent data. The frequency of invasive intestinal amebiasis has been reported to range from 2.2 percent to 16.2 percent in persons with acute diarrhea or dysentery, and the case-fatality rate to range from 0.5 percent in uncomplicated cases to 40.2 percent in persons with amebic dysentery complicated by peritonitis – these figures are drawn from Mexico, Nigeria, Venezuela, and South Africa (reviewed in Muñoz 1986). Although a large number of cases were included in these studies, the populations sampled were biased by including only those admitted to hospitals and healthcare centers.

The frequency of amebic liver abscess is a reliable measure of rates of liver infection, as liver lesions can be identified clinically, in the laboratory, or through post-mortem studies. Liver abscess occurs in c. 2 percent of adult amebiasis patients in endemic areas (Sepúlveda 1982). Elsdon-Dew tabulated the geographical distribution of persons with amebic liver abscesses and concluded that the condition is prevalent in West and South East Africa, South East Asia, Mexico, and the western portion of South America (Elsdon-Dew 1968). Amebic hepatic abscess is at least ten times more common in adults than in children. It predominates in adults aged between 20 and 60 years and within this group, three times as many men suffer from this condition as women. The reasons for the notable differences in the frequency and severity of invasive amebiasis according to age and sex are unknown.

The differentiation between *E. histolytica* and *E. dispar* in areas of high endemicity has already provided relevant epidemiologic information in Mexico (Sánchez-Guillén et al. 2002), Côte d'Ivoire (Heckendorn et al. 2002), Ecuador (Gatti et al. 2002), and Vietnam (Blesmann et al. 2002)

CHEMOTHERAPY

The use of amebicides in the treatment of patients with amebiasis has contributed greatly to reducing the morbidity and mortality of the disease. Antiamebic drugs may be classified into three groups:

1 luminal amebicides
2 tissue amebicides
3 mixed amebicides.

The most frequently used amebicides with luminal action are di-iodohydroxyquin (650 mg orally three times daily for 20 days), diloxanide furoate (500 mg orally three times daily for 10 days) and paromomycin (500 mg orally three times daily for 5–10 days).

Amebicides effective in both tissues and the intestinal lumen include metronidazole and the nitroimidazole derivatives tinidazole and ornidazole. In addition to being active in both tissues and the intestinal lumen, these drugs have the advantage that they are given orally and are most effective therapeutically. They are reasonably well tolerated and despite reported carcinogenic effect in rodents and their mutagenic potential in bacteria, no such effect has been detected in humans. They are, therefore, the drugs of choice in the treatment of invasive amebiasis in spite of some unpleasant, but not serious side-effects. Metrodinazole is given orally 500–800 mg three times a day for 5 days to people with invasive intestinal amebiasis and for 5–10 days to persons with liver abscesses. Tinidazole or ornidazole are administered orally 2 g once a day for 1–3 days. For further details on the chemotherapy of amebiasis, refer to Martínez-Palomo and Ruíz-Palacios (1990).

There is no drug resistance in amebiasis. Those few reports of failed treatment refer to advanced cases in which most of the liver parenchyma was replaced by the amebic abscess and treatment was administered too late. In vitro studies performed with fresh isolates from symptomatic patients and asymptomatic carriers, as well as axenically cultured pathogenic amebae, confirmed drug sensitivity in all cases (Burchard and Mirelman 1988).

Two severe forms of invasive intestinal amebiasis require surgery in addition to chemotherapy: toxic megacolon and amebic appendicitis. Amebic liver abscesses should be treated by chemotherapy; percutaneous or surgical drainage is indicated in cases of imminent rupture.

One of the most striking features of invasive amebiasis, whether intestinal, hepatic or cutaneous, is

that after adequate treatment amebic lesions heal without scarring. There is no apparent explanation of this peculiar aspect of the pathology of the disease.

VACCINATION

Evidence for the existence of acquired immunity against amebiasis is essentially based on two sets of observations. The first is the widely held knowledge that recurrence of amebic liver abscess is exceedingly rare. Although no recent data are available, estimates in the early 1970s in Mexico City indicated that 0.04 percent of patients recovered from an amebic liver abscess had recurrences during a 7-year follow-up period (versus a prevalence of 0.1–0.2 percent of amebic liver abscesses per year in the general population) (reviewed in Kretschmer 1986). The second set of observations supporting acquired immunity is drawn from studies on experimental animals that are refractory to amebic hepatic reinvasion after spontaneous or induced recovery. SCID mice can be partially protected by passive immunization procedures (Cieslak et al. 1992) and partial protection of intact mice has also been obtained through immunization with crude and fractionated preparations of *E. histolytica* and with live trophozoites. Local and systemic antibody responses have been reported to occur in experimental animals after immunization with fixed trophozoites and with an immunogenic peptide fused to the cholera toxin B subunit (Moreno-Fierros et al. 1995; Zhang et al. 1995).

There is also evidence against the development of immunity to invasive amebiasis. Recurrence of amebic hepatic abscesses was documented in a study in Vietnam (Blesmann et al. 2002). The rise in morbidity and mortality due to *E. histolytica* with increasing age, for example, casts some doubt on the concept of effective acquired protective immunity. In addition, it has been observed that not all antibodies are protective, as passive immunization with purified antiamebic immunoglobulins fails to protect hamsters against intrahepatic challenge with *E. histolytica* (Campos-Rodríguez et al. 1995). It has, therefore, been suggested that induction of protective immunity depends on the recognition by antibody of specific molecules. Recombinant peptides of three *E. histolytica* antigens show promise for prevention of experimental amebic liver abscess (reviewed in Stanley 1996): the serine-rich *E. histolytica* protein (SREHP), the 170 kDa subunit of N-acetyl-D-galactosamine inhibitable lectin, the 29 kDa cysteine-rich antigen. Much work still needs to be undertaken before an antiamebic vaccine is produced.

INTEGRATED CONTROL

Transmission of amebiasis may be accomplished through a variety of mechanisms. Asymptomatic carriers passing large numbers of cysts in their stools are important sources of infection, particularly if they are engaged in the preparation and handling of food. The cysts may remain viable and infective for a few days in feces, but are killed by desiccation and temperatures greater than 68°C, so boiled water is safe. The amount of chlorine normally used to purify water is insufficient to kill cysts; higher levels of chlorine are effective, but the water thus treated must be dechlorinated before use. Houseflies and cockroaches ingest cysts present in feces and can pass them from their guts following periods as long as 24 hours.

Fecal contamination of springs, unprotected shallow wells, and streams may occur as a result of surface runoff. Contamination may also result from discharge of sewage into rivers. Occasionally, siphonage of sewage into the water supply system has been responsible for outbreaks of infection. Freshening of vegetables and fruit with contaminated water and using human excreta as fertilizer may produce heavy contamination, a particularly serious problem with vegetables and fruit that are usually eaten raw (Walsh and Martínez-Palomo 1986).

The basic means of preventing amebic infection is the improvement of living conditions and education in countries where invasive amebiasis is prevalent. The main targets should be improvements in sanitation of the environment, detection and treatment of infected persons, and health education.

The most effective preventive measure is the adequate disposal of human feces through proper drainage systems or the use of septic tanks. Purified water should be distributed through pipelines to avoid contamination. In areas where amebic infection is common, drinking water should be boiled for several minutes, or filtered or chlorinated with higher levels of chlorine that those used to eliminate bacterial contamination. People should be instructed to clean and freshen vegetables carefully with uncontaminated running water, because treatment with iodine, chlorine, or silver solutions gives unreliable results. Food handlers should be periodically checked for intestinal infection and treated if found positive. Houseflies and cockroaches should be controlled and food adequately protected from them.

Cases of invasive amebiasis require prompt chemotherapy and it was previously recommended that all asymptomatic carriers of *Entamoeba* be treated. With the development of methods to differentiate between *E. histolytica* and *E. dispar*, *E. histolytica* carriers may be identified and should be treated, whereas *E. dispar* carriers should be monitored closely for the possibility of superinfection with *E. histolytica*. Whether such a course of action will be practicable for general control of amebiasis remains to be seen.

As part of health education of the population, hygienic practices such as hand washing after defecation and before eating, boiling of drinking water, and

avoiding the consumption of raw vegetables and exposed food should be constantly reiterated in schools and healthcare units, and through periodic campaigns in the mass media.

Health personnel should be given training to improve the accuracy of their examination of stools. Doctors should be constantly reminded of the problem of amebiasis and informed of advances in diagnostic and therapeutic procedures; their active participation in prevention programs should be encouraged.

Other intestinal amebae

JOHN P. ACKERS

Introduction and scope	1	Epidemiology and life-cycles	2
Classification	1	Diagnosis	3
Immunology	1	Clinical aspects	3
Biochemistry and molecular biology	2	References	7

INTRODUCTION AND SCOPE

The indubitably pathogenic protozoa that inhabit the human intestine have, quite rightly, received the bulk of our attention, both in research terms and in this volume. Nevertheless, interms of numbers of persons infected, these pathogenic species are dwarfed by the unobtrusive, largely nonpathogenic and little studied organisms that are the subject of this chapter: *Entamoeba coli*, *E. gingivalis*, *E. moshkovskii*, *E. chattoni*, *E. polecki*, *Endolimax nana*, and *Iodamoeba bütschlii*.

In other chapters, the classification, immunology, epidemiology, and any progress towards the development of a vaccine are dealt with separately for each organism. So little is known about these aspects of most of the species considered here, however, that it would be tedious to repeat our ignorance for each one. These aspects are, therefore, considered briefly together before moving on to consider the clinical features of infection by each of these organisms.

CLASSIFICATION

Classically, all the *Entamoeba* are placed in one of the two great branches of the phylum Sarcomastigophora – the subphylum Sarcodina ('ameba'); and within this subphylum successively in the superclass Rhizopoda, class Lobosea, subclass Gymnamoebia, order Amoebida, and sub-order Tubulina (Levine et al. 1980) as are *Endolimax* and *Iodamoeba*. The overall classification of the protozoa is unsatisfactory and that of ameboid organisms perhaps particularly so. However, in the case of the organisms included in this chapter, molecular taxonomy seems to confirm that they are more similar to each other (albeit only distantly related) than to any other major group of eukaryotes and may legitimately be placed in the family Entamoebidae (Silberman et al. 1999). Figure 1 shows that the number of nuclei in the mature cyst, long one of the bases of microscopical diagnosis, is a taxonomically valid character (note, however, that *I. bütschlii* was not included in this analysis).

None of these organisms possess mitochondria and it had been speculated that they and some other anaerobic protozoa were examples of surviving pre-mitochondrial eukaryotes ('Archezoa'). Enough genes of mitochondrial origin have now been observed in all the well-studied members of this group to make it virtually certain that they are descended from organisms that did possess this organelle and although no investigation has been made of the organisms described here, it seems very unlikely that the same is not true of them as well.

IMMUNOLOGY

Essentially, nothing is known of human immune responses to these parasites, although their ubiquity strongly suggests that protective immunity develops only after multiple infections, if at all. This is supported by some data from the Gambia (Bray and Harris 1977), which shows that the percentage of cyst-positive feces increases with age for all the gut protozoa studied (which included *E. coli*, *Endolimax nana*, and *I. bütschlii*)

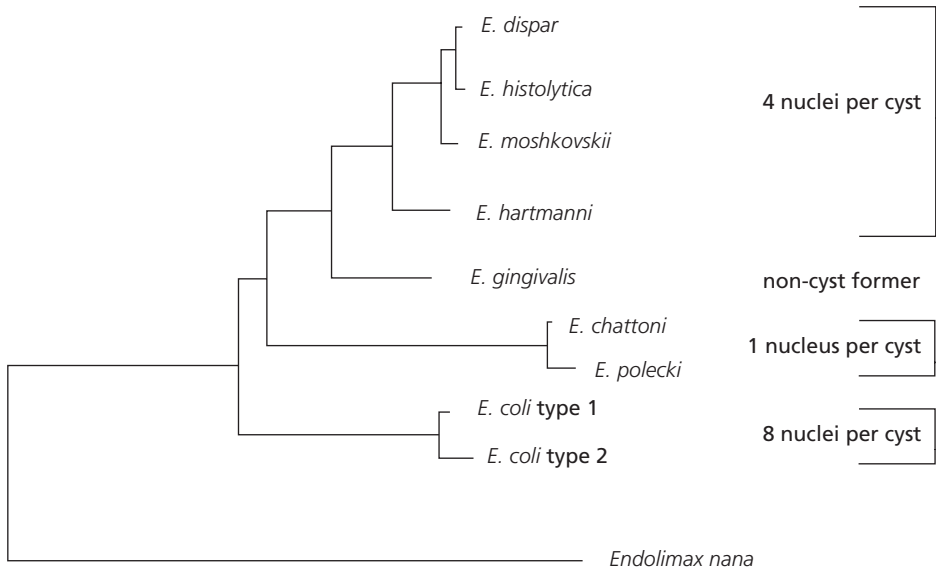

Figure 1 *Phylogenetic tree based on small sub-unit ribosomal RNA sequences, showing the relationship between the* Entamoeba *spp. discussed in this chapter and the number of nuclei in the mature cyst. (Courtesy of Dr Graham Clark, London School of Hygiene & Tropical Medicine; adapted from Silberman et al. 1999)*

except for *Giardia intestinalis*. Importantly, there is no evidence that any of these organisms can become clinically significant even in the presence of severe immunosuppression or clinical acquired immune deficiency syndrome (AIDS). It need hardly be added that there is no current work directed towards developing a vaccine against any of these organisms.

BIOCHEMISTRY AND MOLECULAR BIOLOGY

Again, there is virtually nothing known about the biochemistry of any of these organisms. All may be cultivated (with difficulty in some cases) in complex media in the presence of bacteria (Sargeaunt and Williams 1982; Diamond 1983) but only *E. moshkovskii* can currently be grown axenically (Diamond et al. 1995) and this has greatly hindered studies of metabolic pathways. The very limited amount of published molecular biological data suggests that these organisms may well share the peculiarities (such as ribosomal RNA genes carried on circular episomes) of *E. histolytica*. A comparative *Entamoeba* genome sequencing project, which includes *E. moshkovskii*, is underway at the Sanger Institute (www.sanger.ac.uk/Projects/Comp_Entamoeba/) and this will greatly increase our knowledge of at least this species.

EPIDEMIOLOGY AND LIFE-CYCLES

With the exception of *E. gingivalis* (see below), infection with all of these organisms is assumed to be acquired by oral ingestion of fecally contaminated food or drink. Although no human volunteer studies have been carried out to prove this, the epidemiology of the infections and their close similarities to *E. histolytica*/*dispar*, where this has been demonstrated, support this. The life cycle is simple: excystment occurs, possibly as with *E. histolytica* in the small bowel, and the organisms then live as trophozoites in the lumen of the large bowel. There is no evidence that any of these organisms can invade the mucosa while the host is alive although they may do so rapidly after death (Vogel et al. 1996). Responding to unknown stimuli, trophozoites round up and secrete a resistant wall, becoming the cysts which, when shed in the feces, are responsible for transmitting the infection. Nuclear division frequently occurs following encystment to produce the characteristic numbers of nuclei so important in microscopical diagnosis. Although morphologically similar cysts are found in the feces of many wild and domestic animals, with the further exception of *E. chattoni* and *E. polecki* (see below), there is no evidence that animal reservoirs are important in the epidemiology of human infections (but also no evidence that they are not).

In a fascinating study, Garrido-Gonzalez et al. (2002) measured the cyst output from a number of infected persons. The results are complex but, in summary are thus:

- cyst excretion varies greatly between patients but a small group of persons produce a majority of the cysts
- cyst excretion varies widely over time and tends to occur in bursts

- in mixed infections cyst excretion by both species is affected
- different parasites produce different average numbers of cysts with *Endolimax nana* > *E. coli* > *E. histolytica*/*dispar* .

These results, which are supported by earlier and largely forgotten studies, clearly have implications for both diagnosis and prevention strategies.

DIAGNOSIS

In anything other than research settings, diagnosis of all these organisms except *E. gingivalis* is by microscopical examination of feces and is based on cyst morphology. Detailed protocols may be obtained from standard texts (Garcia and Bruckner 1997) or from the Centers for Disease Control and Prevention (CDC) (www.dpd.cdc.gov/dpdx/HTML/DiagnosticProcedures.htm) but, in outline, specimens should be stained with iodine and, if possible, a cyst concentrate should also be examined. Measurement of cysts is essential for accurate diagnosis, along with nuclear number and morphology.

Since it produces no cysts, diagnosis of *E. gingivalis* relies on trophozoite morphology; however, this is not distinctive (see below). As in all such cases, the trophozoites need either to be examined very shortly after the specimen is obtained or fixed immediately before being stained and examined at leisure.

Cultivation of these organisms, although not usually feasible routinely, has two advantages – it provides a (probably modest) increase in sensitivity and, more importantly, it allows much more accurate species diagnosis to be made based on methods such as isoenzymes, riboprinting and polymerase chain reaction (PCR) although this is exclusively carried out in a research setting. Protocols that allow the extraction of DNA directly from fecal samples and its use for PCR-based diagnosis of *E. histolytica* and *E. dispar* are now in routine use and could certainly be adapted for the nonpathogenic ameba if there were any demand for this.

CLINICAL ASPECTS

All of these organisms are regarded as nonpathogenic (occasional reports to the contrary are given below) and the advice from CDC is that persons infected with *E. coli*, *E. polecki*, *Endolimax nana* or *I. bütschlii* should not be treated (www.cdc.gov/ncidod/dpd/parasites/amebae/factsht_amebae.htm). Their presence is, however, evidence that close contact with fecally contaminated material has occurred and might prompt a more thorough search for pathogenic species. There seems no reason to doubt that the luminal amebicides such as paromomycin and diloxanide furoate would be effective if used. As would be anticipated, metronidazole appears to be effective in eliminating oral infection with *E. gingivalis* in the small number of reported cases where this was attempted (Sefer et al. 1989; el Azzouni and el Badry, 1994).

Clinical manifestations

ENTAMOEBA COLI

Entamoeba coli competes with *Endolimax nana* for the title of the world's commonest intestinal protozoan, with average incidence figures of 27 percent in a large number of older surveys (Levine 1973) and up to 40 percent reported in some populations; even in 1987, 4 percent of routine fecal samples taken in the US contained this parasite (Kappus et al. 1994). Apparently identical cysts have been found in the feces of many primates and, rarely, of other mammals. Typical cysts (Figure 2) are easy to identify being large (15–25 μm in diameter) and having eight smallish nuclei of one-sixth to one-eighth the cyst diameter. Peripheral chromatin is less regularly spread around the nuclear membrane than in *E. histolytica* cysts; chromidial bars, if present, have splintered rather than rounded ends. Occasionally, cysts may contain fewer than eight, or up to 16 nuclei; cyst size may be quite variable (Garrido-Gonzalez et al. 2002) and those 15 μm or less in size may be harder to distinguish from *E. histolytica*/*dispar*.

Trophozoites are usually 20–25 μm long with granular cytoplasm containing ingested bacteria, yeasts and other debris, but very rarely erythrocytes; in infected humans, trrophozoites are found in the cecum and colon. The single nucleus contains a large karyosome; blunt pseudopodia are extended in a sluggish, randomly directed manner. Although easily cultivated in bacteria-

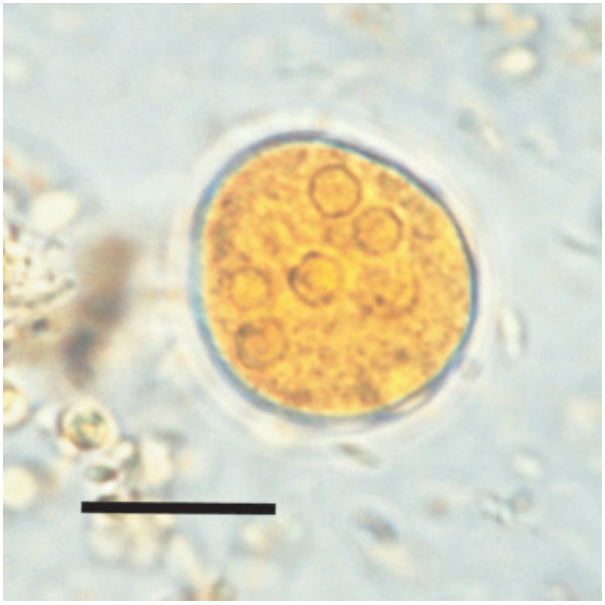

Figure 2 *Cyst of* E. coli*, wet preparation stained with iodine. Bar = 10 μm.*

containing media, very little work has been devoted to this common parasite and almost nothing is known of its cell biology. After being cultured, it may be distinguished from *E. histolytica* by isoenzyme analysis (Sargeaunt and Williams 1978), several monoclonal antibodies and riboprinting (Clark and Diamond 1992).

E. coli is normally regarded as wholly harmless, although two isolated reports (Wahlgren 1991; Corcoran et al. 1991) have suggested that it might be an occasional cause of diarrhea. In this, as in so many other cases, the evidence consists of symptomatic patients in whom no other pathogen could be identified and in whom treatment resulted in clinical cure accompanied by loss of the infection. There are a number of weaknesses with this kind of argument – however thoroughly cases of diarrhea are studied, in about 25 percent of them no pathogen can be demonstrated, and drugs such as metronidazole have a very broad spectrum of activity against a wide variety of gastrointestinal organisms. However, while *E. coli* clearly does not produce illness in the majority of those who carry it, that is not say that it cannot be pathogenic in some.

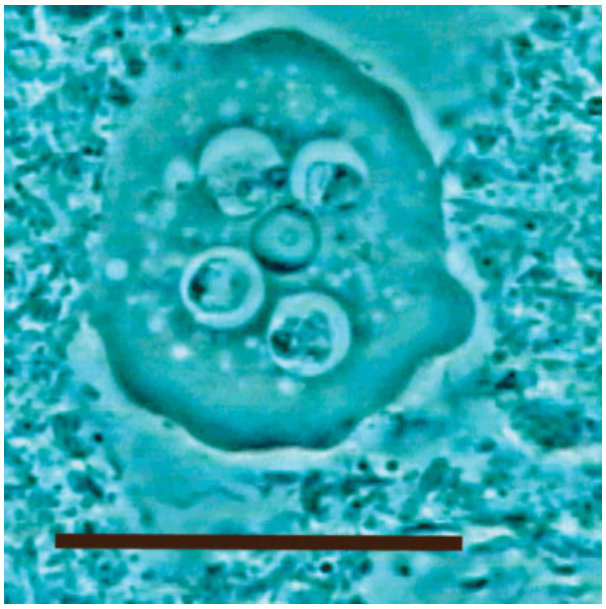

Figure 3 *Trophozoite of* E. gingivalis *in scrapings from a case of severe periodontal disease. Bar = 10 μm. (Courtesy of Dr Mark Bonner, Institut International de parodontie, Quebec)*

ENTAMOEBA GINGIVALIS

E. gingivalis is unusual among the *Entamoeba* in two respects – first, it inhabits the mouth rather than the large bowel; secondly, no cyst of *E. gingivalis* has ever been found. Transmission is presumably by direct mouth-to-mouth contact and, since the trophozoite is never exposed to desiccation or other unfavorable conditions, a resistant cyst is not needed. No selection pressure to maintain the ability to encyst therefore exists and so, like most redundant functions, it has probably been lost (Clark and Diamond 1997).

Trophozoites of this species may be recovered from the mouths of a significant percentage of patients with periodontal disease (Levine 1973; Favoreto and Machado 1995) and, although it is normally regarded as a harmless commensal that finds an ideal home among diseased gums (Pomes et al. 2000), some believe that it has a directly pathogenic role. Frequency of isolation appears to increase with age, possibly reflecting deteriorating condition of the gums and *E. gingivalis* has been implicated in the severe periodontal disease suffered by some human immunodeficiency virus (HIV)-positive patients (Lucht et al. 1998) and may even spread outside the oral cavity following radiotherapy (Perez Jaffe et al. 1998). *E. gingivalis* has also been recovered from the vaginas of a small number of women using intra-uterine devices and who have concomitant bacterial infections (deMoraes Ruehsen et al. 1980; Clark and Diamond 1992). In these cases, *E. gingivalisis* is presumed to have been acquired by orogenital contact.

The trophozoite of *E. gingivalis* (Figure 3) is about 10–20 μm long with a typical *Entamoeba* nucleus. A number of xenic media for its cultivation exist and it may be distinguished from other species by isoenzyme patterns, riboprinting, and PCR (Kikuta et al. 1996) By light microscopy, the trophozoites are not distinguishable from *E. histolytica* except in that they are frequently seen to have ingested both erythrocytes and leukocytes whereas *E. histolytica* when isolated from patients (but not in vitro) appears to ingest only the former (Dao 1985).

ENTAMOEBA MOSHKOVSKII

This organism was first isolated from the sewers of Moscow in 1941, but has subsequently been recovered from the same source in many parts of the world (Levine 1973). Its presence in sewers was a great mystery because no human excretors had ever been found. However, it is now known to be ubiquitous in both fresh and brackish anoxic environments. It may be grown in axenic culture and its optimum growth temperature is about 24°C.

Up to 1998, seven isolates of organisms (originally assumed to be *E. histolytica*) with the unusual property of being able to grow at room temperature and in hypotonic media had been recovered from asymptomatic human carriers. These organisms, referred to as atypical, *E. histolytica*-like or 'Laredo-type' (after the original isolate) are of low pathogenicity in laboratory animals, resistant to a number of drugs and differ antigenically from classical *E. histolytica* or *E. dispar* (Goldman 1969). In 1980, Sargeaunt et al. showed that the isoenzyme patterns of five such isolates were all very similar to that of two *E. moshkovskii* strains; Sargeaunt et al. (1982) and Clark and Diamond (1991) proved that the 'Laredo-type' and *E. moshkovskii* are the same species.

Both trophozoites and cysts of *E. moshkovskii* resemble those of *E. dispar*. The active trophozoites are usually 11–13 μm long; the cysts spherical, 7–17 μm in diameter and containing a large glycogen vacuole when fresh (Figure 4). The mature cysts contain four nuclei; chromidial bodies, if present, have rounded ends (Levine 1973). Unless they are cultured and their isoenzymes or other defining properties are tested, the organisms are likely to be identified as *E. dispar*. Epidemiologically, *E. moshkovskii* is presumably either a free-living species that is an occasional human parasite (apparently, it may be adapted to grow well at 37°C (Lachance 1959)) or a true human parasite which, because of its tolerance of low temperature and hypotonicity, can persist indefinitely outside its host(s). The latter possibility has been rendered much more likely by the recent and wholly unexpected finding that over 20 percent of a group of pre-school children in Bangladesh were infected with *E. moshkovskii* (Ali et al. 2003). The nested PCR diagnostic procedure developed by these authors should make it much easier to see if this situation exists in other populations.

One other Laredo-type human isolate – *E. ecuadoriensis* – is known; it possesses the same culture tolerance as *E. moshkovskii* but by both isoenzyme analysis (Sargeaunt et al. 1980) and riboprinting (Clark and Diamond 1991) is clearly distinct from all other known species of *Entamoeba*.

ENTAMOEBA POLECKI AND *ENTAMOEBA CHATTONI*

Entamoeba polecki (for which some authors prefer the name *Entamoeba suis* (Levine 1973) is a common parasite of the cecum and colon of pigs, where it apparently causes little or no pathology. The trophozoites may be 10–25 μm long (although they usually measure 12–18 μm) with vacuolated cytoplasm; the cyst (Figure 5) is usually 9–15 μm in diameter with a single nucleus even when mature. The nuclear endosome is usually quite large; glycogen granules and chromidial bodies may or may not be present (Noble and Noble 1952). The nucleus is 25–33 percent of the diameter of the whole cyst, compared with the relatively larger (33–50 percent) nucleus of the immature, uninucleate cyst of *E. histolytica*. However, the differences are subtle and, indeed, the parasites grown from one such specimen were isoenzymically indistinguishable from *E. histolytica* (Sargeaunt et al. 1980).

Entamoeba chattoni is an equally common parasite of wild primates (Levine 1973; Jackson et al. 1990), which is also found in captive animals. The cyst (Figure 6) is 6–18 μm in diameter, usually containing only one nucleus with a very variable appearance.

Both species have occasionally been reported from human feces; *E. polecki* most often in SE Asia (Desowitz and Barnish 1986; Muller et al. 1987; Barnish and Ashford 1989) or in refugees from that region (Chaker et al. 1982; DeGirolami and Kimber 1983), although it has also been reported from France (Masure et al. 1980) and Venezuela (Chacin Bonilla et al. 1992). No definite pathology has been linked to this organism. A small number of human infections with *E. chattoni* have also been described, mostly in those with occupational exposure to primates (Burrows and Klink 1955; Sargeaunt et al. 1992); some patients had diarrhea but whether or not this was due to the ameba is not clear.

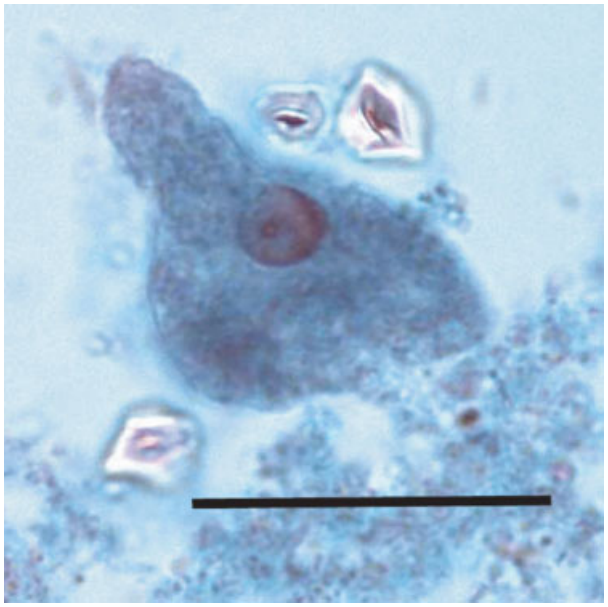

Figure 4 *Trophozoite of* E. moshkovskii *in culture. Bar = 10 μm. (Courtesy of John Williams, London School of Hygiene & Tropical Medicine)*

Figure 5 *Cyst of* E. polecki, *wet preparation stained with iodine. Bar = 10 μm. Note that these cysts and those of* E. chattoni *(Figure 6) are not morphologically distinguishable. (Courtesy of John Williams, London School of Hygiene & Tropical Medicine)*

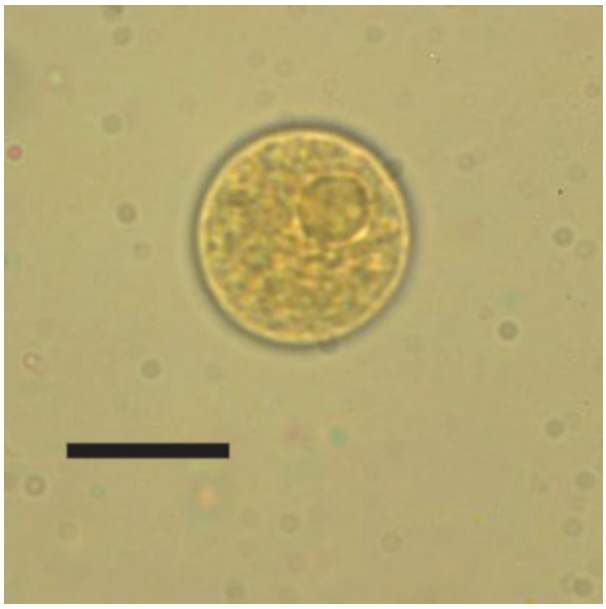

Figure 6 *Cyst of* E. chattoni*, wet preparation stained with iodine. Bar = 10 μm. (Courtesy of Dr Jaco Verweij, Centrum voor Infectieziekten, Afdeling Parasitologie, Universiteit Leiden)*

Although human infections with *E. polecki* and *E. chattoni* seem to be linked to exposure to different reservoir hosts, the cysts of both species are microscopically indistinguishable (Burrows 1959). Recently, therefore, species-specific PCR primers were developed to distinguish reliably between the two (Verweij et al. 2001). A most surprising result to emerge from this work was that, of 12 human fecal samples obtained from the Netherlands that were microscopically positive for uninucleate *Entamoeba* cysts, only one was infected with *E. polecki* and two with *E. chattoni*. The remainder were infected with two distinct *Entamoeba* species which, while clearly clustering with *E. polecki* and *E. chattoni*, were identical with neither. These results suggest that other related *Entamoeba* species can also infect humans; the authors suggest that, for the present, all such uninucleate cysts should be reported as '*E. polecki*-like.'

ENDOLIMAX NANA

Endolimax nana is a small, frequently reported ameba that is diagnosed in humans about as often as *E. coli* (Levine 1973; Kappus et al. 1994); similar if not identical parasites are also found in primates and pigs (Levine 1973). Both cysts and trophozoites possess a characteristic limax nuclear morphology that must be recognized to make an accurate diagnosis of fecal specimens. Limax nuclei have a large, irregularly-shaped mass of chromatin (the karyosome or endosome), which may be either centrally or eccentrically placed but there is no peripheral chromatin, so the nuclear membrane is all but invisible. The ring-shaped nucleus typical of *Entamoeba* and *Giardia* species is not seen; instead, wet preparations stained with iodine reveal the nuclei as dark, soft-edged specks which 'blink' into and out of view as the microscope is focused up and down.

Endolimax nana cysts may be ellipsoidal, spherical or irregular with a longest dimension of 6–10 μm, although it is usually less than 10 μm (Figure 7). They are thin-walled and almost always contain four limax-type nuclei, never more – smaller, thick-walled bodies with more than four dark nuclei are of fungal origin. Trophozoites are usually 8–10 μm long with a single limax nucleus and granular cytoplasm; they move sluggishly by extending blunt pseudopodia. The organism may be cultivated in bacteria-containing media and an isoenzyme pattern has been published (Sargeaunt and Williams 1979); otherwise nothing is known of the metabolism.

This organism is normally regarded as nonpathogenic although there are isolated reports of gastrointestinal symptoms in AIDS patients for which no other cause could be found (Rolston et al. 1986; Peters et al. 1987). Reports of *Endolimax nana* being responsible for urticaria (Veraldi et al. 1991) and rheumatism (Burnstein and Liakos 1983; Alarcon Segovia and Abud Mendoza 1985) have yet to be confirmed.

IODAMOEBA BÜTSCHLII

Trophozoites and, above all, cysts of *I. bütschlii* contain glycogen that is colored deep brown in the usual iodine-stained wet preparations and gives the genus its name. Trophozoites are usually 12–15 μm long with a single nucleus containing a large karyosome and granules visible in permanent stained preparations; the cytoplasm may be coarse with ingested bacteria and glycogen-

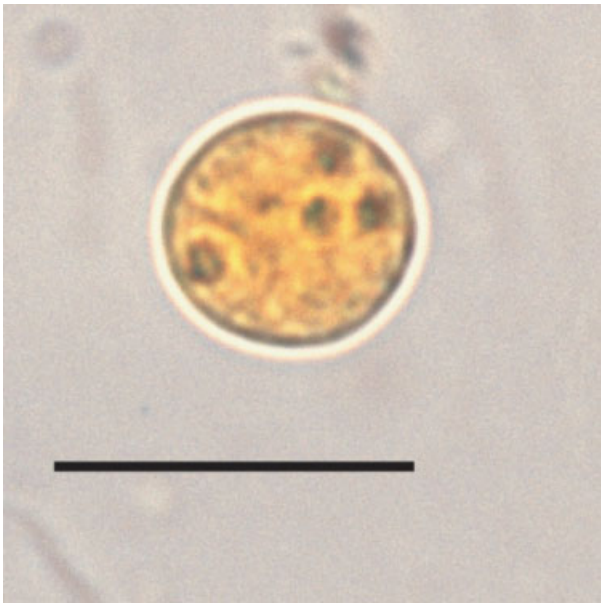

Figure 7 *Cyst of* Endolimax nana*, wet preparation stained with iodine. Bar = 10 μm. (Courtesy of John Williams, London School of Hygiene & Tropical Medicine)*

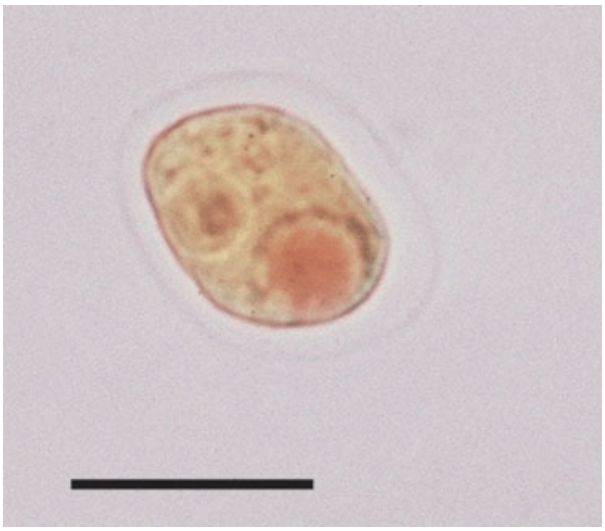

Figure 8 *Cyst of* I. bütschlii*, wet preparation stained with iodine. Bar = 10 μm. (Courtesy of John Williams, London School of Hygiene & Tropical Medicine)*

containing vacuoles. Cysts (Figure 8) are usually 9–12 μm across, often round or oval but not unusually very irregular with a single, limax-type nucleus containing a large central or eccentric karyosome. The glycogen vacuole is large and compact with a clearly defined edge; it stains deeply with iodine when the cysts are fresh but may disappear if they are stored for more than a few days. Distinction from other species is normally easy but may be difficult if immature, uninucleate *E. histolytica*/*E. dispar* cysts are present; these often contain glycogen stores, which will be used up as they mature, but this glycogen is usually present as a more diffuse, less deeply staining mass.

I. bütschlii is not rare in human feces but is usually reported in only a few percent of fecal samples from developing countries or from male homosexuals; identical cysts are found in the feces of several primates and the organism is (or was) very common in pigs all over the world. All such parasites are assigned to the same species but no evidence of human infections from animal reservoirs has been presented. The isoenzyme profile of an isolate has been published (Sargeaunt and Williams 1979).

I. bütschlii is not normally regarded as a pathogen (a disseminated infection and cerebral granuloma attributed to it were probably caused by an *Acanthamoeba* species, see Opportunistic amebae) but has occasionally been proposed as a cause of diarrhea (Andrew 1947; Rolston et al. 1986).

INTRODUCTION

Free-living amebae of the genera *Naegleria*, *Acanthamoeba*, and *Balamuthia* can cause disease in humans and other animals. Normally, they live as phagotrophs in aquatic habitats where they feed on bacteria but as opportunists, they may produce serious infection of the central nervous system (CNS) and the eye. The term amphizoic (from Greek 'amphi' meaning 'on both sides') has been proposed to describe the ability of these amebae to live in two worlds, as free-living organisms and as endoparasites (Page 1974).

Naegleria fowleri is responsible for a rapidly fatal infection involving the CNS and called primary amebic meningoencephalitis (PAM). Infection occurs most often in healthy young people who have a recent history of swimming in freshwater. Several species of *Acanthamoeba* cause disease. *Acanthamoeba* may produce a chronic CNS infection known as granulomatous amebic encephalitis (GAE) or an eye infection referred to as *Acanthamoeba* keratitis. Human infections originally attributed to *Hartmannella*, another free-living ameba, were actually caused by *Acanthamoeba*. *Balamuthia mandrillaris*, a leptomyxid ameba (Visvesvara et al. 1993), causes a chronic CNS infection similar to that produced by *Acanthamoeba*, also termed GAE. Additional reports have described eye infections caused by *Hartmannella* and *Vahlkampfia* (Aitken et al. 1996; Inoue et al. 1998), a fatal CNS infection caused by *Hartmannella vermiformis* (Centeno et al. 1996) and a nonfatal encephalitis caused by *Sappinia diploidea* (Gelman et al. 2001).

CLASSIFICATION

The classification of the Protozoa is in a state of flux and, following the precedents set out elsewhere in this volume (see Classification and introduction to the parasitic protozoa), the scheme proposed by Corliss (1994) and widely adopted by scientists working with free-living protozoa is used in this chapter. On the basis of the traditional classification published by the Society of Protozoologists (Lee et al. 1985), all the opportunistic amebae were classified in the phylum Sarcomastigophora and subphylum Sarcodina, which contained two classes, class Lobosea and class Acarpomyxea. Class Lobosea contained two orders: order Amoebida (family Acanthamoebidae, e.g. *Acanthamoeba*) and order Schizopyrenida (family Valkampfidae, e.g. *Naegleria*). Class Acarpomyxea contained the order Leptomyxida (family Leptomyxidae, e.g. *Balamuthia*). In Corliss' classification both *Acanthamoeba* and *Balamuthia* are classified in the phylum Rhizopoda, class Lobosea, and *Naegleria* has been moved to the phylum Percolozoa and placed in the class Heterolobosea and order Schizopyrenida.

STRUCTURE AND LIFE-CYCLES

Morphology

The nuclei of the opportunistic amebae are characterized by a large central nucleolus or karyosome, and a nuclear membrane without chromatin granules. These features are especially useful when examining histological sections as they readily distinguish the opportunistic amebae from *Entamoeba histolytica*, the most important parasitic ameba of humans.

NAEGLERIA

The trophozoites of *N. fowleri* are known as limax amebae (from the Latin for 'slug'). These amebae are elongate and move in a directional manner by eruptive, blunt pseudopodia, called lobopodia. Actively moving amebae average about 22 μm in length (range 15–30 μm); inactive, rounded forms range from 9 to 15 μm in diameter (Carter 1970).

Trophozoites of pathogenic *Naegleria* have distinctive phagocytic structures known as amebostomes (Figure 1) (John et al. 1985). Amebostomes are used for engulfment and vary in number, depending on the strain. By transmission electron microscopy, amebostomes appear to be densely granular in contrast to the highly vacuolated body of the ameba. Amebostomes are visible by light microscopy but appear as thick-walled vacuoles. Similar food cups or phagocytic stomata occur on *E. histolytica* (Gonzalez-Robles and Martinez-Palomo 1983).

Reproduction in *Naegleria* is by simple binary fission of the trophozoite. Nuclear division is promitotic, which means that the nucleolus and the nuclear membrane persist during nuclear division (karyokinesis). The nucleolus elongates, forming a dumbbell-shaped structure, and divides into two polar masses, or nucleoli. During this process, the nuclear membrane remains intact (Page 1988).

When *Naegleria* are suspended in distilled water or non-nutrient buffer, they transform into temporary flagellated forms. The typical *N. fowleri* flagellate is a bluntly elongate cigar- or pear-shaped cell with two flagella emerging from beneath the anterior rostrum (Figure 2). Of the different species of *Naegleria*, *N. fowleri* flagellates are the most uniform, generally having two flagella (John et al. 1991).

The cysts of *N. fowleri* (Figure 3) are spherical, often clumped closely together, and are 7–15 μm in diameter (Carter 1970; Page 1988). Examination of cysts by electron microscopy reveals an average of fewer than two mucoid-plugged pores or ostioles per cyst and a relatively thin cyst wall (Schuster 1975), a feature that makes *N. fowleri* cysts susceptible to desiccation.

ACANTHAMOEBA

A feature that readily distinguishes the amebae of *Acanthamoeba* from those of *Naegleria* is the presence of acanthopodia (from Greek 'acanth-' meaing 'spine or thorn'), tapering spike-like pseudopodia (Figure 4). In contrast to *Naegleria*, which has rapid, directional locomotion, *Acanthamoeba* moves slowly on a broad front without direction. Trophozoites of *Acanthamoeba* are larger than those of *Naegleria* and average about 24–56 μm in length (Lewis and Sawyer 1979). Nuclear division in *Acanthamoeba* is metamitotic (i.e. the nucleolus and the nuclear membrane disintegrate during early karyokinesis), a pattern similar to that of dividing metazoan cells (Page 1988).

Considerable variation in cyst morphology occurs among the different species of *Acanthamoeba*, resulting in the naming of new species. Page (1967) recognized four species of *Acanthamoeba*; by 1976 he had recorded seven. On the basis of morphology and isoenzyme analysis, De Jonckheere (1987) identified 17 species of *Acanthamoeba*, of which seven have been associated with human infection. The cysts of *Acanthamoeba* are double-walled and, therefore, quite resistant in the environment. The cyst wall is made up of an outer, wrinkled or rippled ectocyst and an inner endocyst. The encysted ameba conforms to the shape of the endocyst.

Figure 2 *SEM of a* Naegleria fowleri *flagellate with two flagella emerging from beneath the anterior rostrum. Bar = 3 μm*

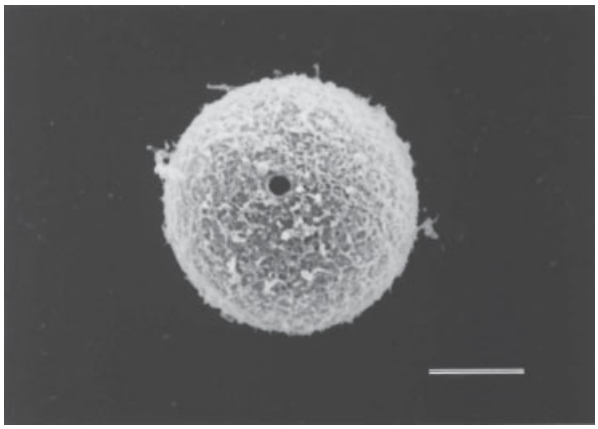

Figure 3 *SEM of a* Naegleria fowleri *cyst with a single pore or ostiole. Bar = 3 μm*

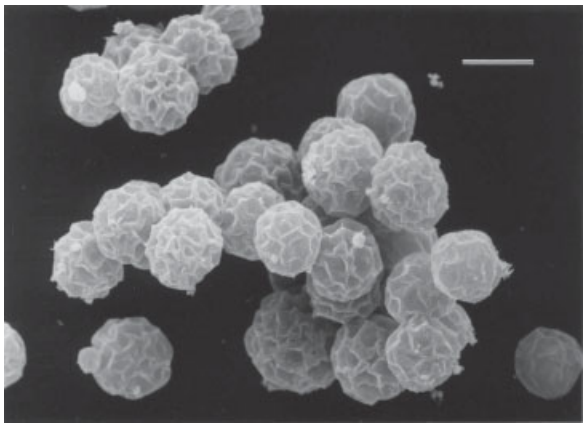

Figure 5 *SEM of pathogenic* Acanthamoeba polyphaga *cysts. Bar = 10 μm*

The characteristic wrinkled appearance of *Acanthamoeba* cysts is readily seen in culture (Figure 5) and in histological sections (see Figure 11).

BALAMUTHIA

The trophozoites of *B. mandrillaris* are mostly irregular or branching in shape (Figure 6), with some limax forms. Their length ranges from 12 to 60 μm (mean c. 30 μm) (Visvesvara et al. 1993). These amebae exhibit little directional motility, although a spider-like walking movement may be seen with amebae grown in Vero cell culture. Nuclear division is metamitotic, as in *Acanthamoeba*. Cysts are irregularly round and are 6–30 μm in diameter (mean 15 μm) with two walls. The inner cyst wall is thin and spherical and the outer cyst wall is thick and wavy or wrinkled (Figure 6) much like the cysts of *Acanthamoeba* (Visvesvara et al. 1993).

Life-cycles

Naegleria, *Acanthamoeba*, and leptomyxid amebae are distributed worldwide in freshwater and soil. *Acanthamoeba* and some leptomyxids are found in marine environments as well. Life-cycles are simple; a feeding trophozoite, or ameba, a resting cyst and, in *Naegleria*, a transient flagellate.

NAEGLERIA

The life-cycle of *N. fowleri* is illustrated in Figure 7. The term 'ameboflagellate' is used to describe amebae that can transform into flagellates. When *Naegleria* amebae are placed in a non-nutrient medium, such as distilled water or buffer, they differentiate into transient, nonfeeding, nondividing flagellates that, after a time, revert back to amebae. Amebae also encyst when conditions are appropriate and, later, excyst in a favorable environment.

The invasive stage of *N. fowleri* is the ameba and infection is acquired by exposure of the nasal passages to the amebae in fresh water. The amebae invade the nasal mucosa, the cribriform plate and the olfactory bulbs of the brain. It is likely that flagellates or cysts of

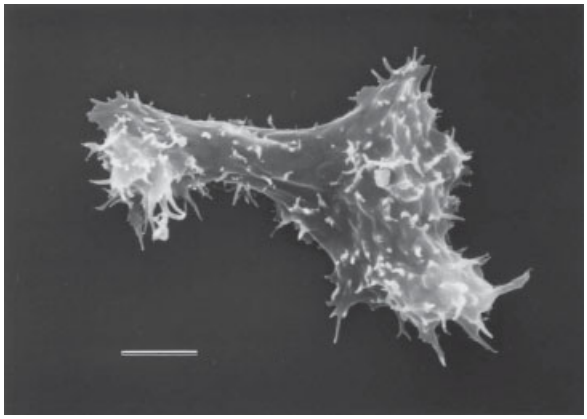

Figure 4 *SEM of a pathogenic* Acanthamoeba castellanii *ameba displaying numerous acanthopodia. Bar = 5 μm*

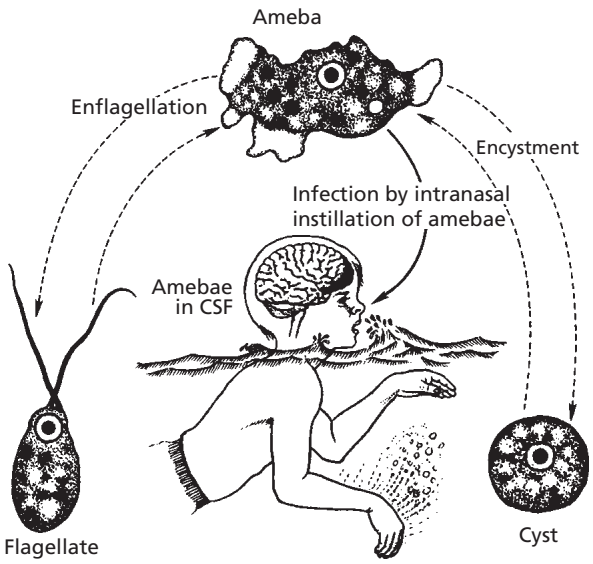

Figure 7 *Life cycle of* Naegleria fowleri *and human infection*

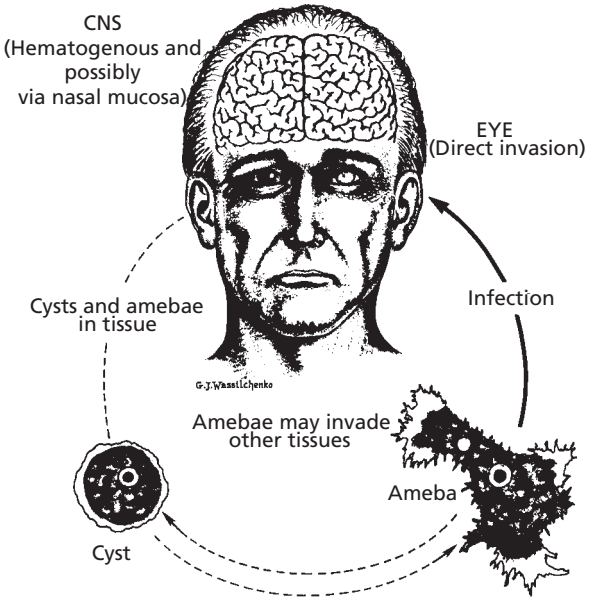

Figure 8 *Life cycle of* Acanthamoeba *spp. and human infection*

N. fowleri could enter the nose of a swimmer as readily as amebae. However, flagellates would revert quickly to amebae or the amebae could escape from cysts, the point being that amebae are the invading organisms. Flagellates or cysts of *N. fowleri* have never been found in tissue or cerebrospinal fluid.

ACANTHAMOEBA AND *BALAMUTHIA*

Figure 8 illustrates the life-cycle of *Acanthamoeba* and shows human involvement. The free-living cycle of the ameba and cyst is also reflected in human infection, in which both amebae and cysts are seen in tissue, in contrast to naeglerial infection in which only amebae occur. *Acanthamoeba* seems to be truly amphizoic in all respects. Amebae and cysts of *Balamuthia* are also found in tissue.

Human infection by *Acanthamoeba* involves the CNS, the eye and other organs. Although amebae of pathogenic *Acanthamoeba* are able to invade the nasal mucosa and cause fatal CNS disease in experimental animals, this is not thought to be the usual route of invasion in human infection. Invasion of the CNS seems to be by way of the circulation, the amebae originating from a primary focus elsewhere in the body, possibly the lower respiratory tract, ulcers of the skin or mucosa or other wounds. The modes of invasion by leptomyxid amebae are thought to be the same. GAE tends to occur in persons who are debilitated, chronically ill or immunocompromised. *Balamuthia* infections occur in both immunosuppressed and immunocompetent persons. In contrast, *Acanthamoeba* keratitis usually occurs in healthy individuals and infection is by direct invasion of the cornea through trauma to the eye or the wearing of contaminated contact lenses.

BIOCHEMISTRY, MOLECULAR BIOLOGY, AND GENETICS

Most research on the cell and molecular biology of free-living amebae has been with nonpathogenic rather than pathogenic species. Nonetheless, some observations can be made and comparisons drawn between the two groups.

Cell differentiation

Cell differentiation is the process by which amebae become cysts or flagellates and, of course, then become amebae again. *Acanthamoeba*, *Balamuthia*, and *Naegleria* all produce cysts, but only *Naegleria* produces flagellates. Thus, free-living amebae provide useful models for studying the developmental biology and molecular mechanisms controlling morphogenesis and differentiation in eukaryotic cells.

ENCYSTMENT

Encystment is an adaptive mechanism that enables the organism to survive conditions that would kill the ameba. Factors thought to induce cyst formation include starvation, drying and various chemicals. Excystment is the process by which amebae exit from their protective cysts. It is generally held that unfavorable conditions induce encystment and that favorable conditions stimulate excystment.

There are no definitive studies that describe the conditions for encystment and excystment in *N. fowleri*. Chemical factors that induce encystment in *A. castellanii* include inhibitors of DNA synthesis – fluorodeoxy-

uridine, mitomycin C, trenimon (Neff and Neff 1972) and hydroxyurea (Rudick 1971); the mitochondrial inhibitors – diminazine (berenil), ethidium bromide, erythromycin, and chloramphenicol (Akins and Byers 1980); and acetate and glucose starvation (Byers et al. 1980). Medium from encysting cultures of *A. castellanii* contains an extracellular encystment-enhancing activity that stimulates cyst formation in early log phase cultures (Akins and Byers 1980). Encystment-enhancing activity is required for encystment in cultures induced by diminazine and by glucose starvation, but not when it is induced by total deprivation of nutrients (Akins et al. 1985).

ENFLAGELLATION

Although spontaneous enflagellation occurs in cultures of *Naegleria*, especially exponential phase cultures of *N. fowleri*, synchronized enflagellation may be achieved by suspending amebae in distilled water or non-nutrient buffer. Enflagellation in *Naegleria* apparently occurs not as an obligatory phase in the life cycle but as a response to changes in the environment. Factors affecting enflagellation in *N. fowleri* include: nutrient depletion, temperature, phase of growth, and culture agitation. Maximum enflagellation in axenically grown *N. fowleri* occurs 4–5 hours after suspension in buffer (Cable and John 1986). For axenically grown nonpathogenic *N. gruberi*, maximum enflagellation occurs somewhat sooner, c. 1.5 hours after suspension in buffer (Fulton 1977).

Cyclohexamide and actinomycin D completely prevent enflagellation in *N. fowleri* when added before enflagellation commences but, when added after initiation of enflagellation, both prevent further differentiation and cause existing flagellates to revert to amebae (Woodworth et al. 1982a). The ultrastructure of *N. fowleri* flagellates is that of a typical eukaryotic protist. There is a distinct nuclear membrane and a prominent nucleolus, numerous vacuoles and cytoplasmic inclusions, pleomorphic mitochondria and some rough endoplasmic reticulum. Basal bodies, rootlets, and flagella are formed quickly after an initial lag of 90 minutes (Patterson et al. 1981).

Macromolecular composition

Changes in cell composition of *N. fowleri* are related to culture age. For shaken axenic cultures, average cell mass remains constant during logarithmic growth at 150 pg per ameba but decreases by 30 percent during the stationary phase at 96 hours. During logarithmic growth, 80–85 percent of the cell dry mass is protein (120 pg per ameba) (Weik and John 1978). Cell dry mass and protein of *N. fowleri* are c. 70 percent of values reported for *N. gruberi* (Weik and John 1977). The majority of *N. fowleri* polypeptides have molecular masses within the range of 20–60 kDa (Woodworth et al. 1982b). During logarithmic and stationary phases of growth of *N. fowleri*, carbohydrate content averages 15 pg per ameba and RNA is c. 18 pg per ameba (Weik and John 1978). By comparison, *N. gruberi* carbohydrate averages c. 35 pg per ameba and the RNA content is 8 pg per ameba (Weik and John 1977). The more than two-fold higher RNA value for the smaller pathogenic *N. fowleri* reflects different biosynthetic capabilities and maintenance of a larger ribosome complement. Total DNA in *N. fowleri* is 0.2 pg per ameba during logarithmic growth; it doubles during transition from exponential phase to stationary phase and then gradually decreases almost to initial levels. The peak in DNA content corresponds to an increase in the average number of nuclei per ameba; nuclear number then decreases as cells enter the stationary phase (Weik and John 1978). In *N. gruberi*, the total DNA content of 0.2 pg per cell increases by 50 percent during exponential growth (Weik and John 1977).

RESPIRATORY METABOLISM

As an opportunistic pathogen, *N. fowleri* lives in the brain, an oxygen-rich environment, and would thus be expected to have an aerobic metabolism. The use of the synonym '*N. aerobia*' (Singh and Das 1970) recognized the aerobic nature of the organism, in contrast to the anaerobic nature of strictly parasitic amebae. Unlike *E. histolytica*, an anaerobic parasite that lacks mitochondria, *N. fowleri* lives in aerobic aqueous environments and has many mitochondria.

Whole-cell respiration rates were measured polarographically throughout the growth cycle of *N. fowleri* (Weik and John 1979a). In agitated cultures, amebae consume 30 ng atoms O per minute per mg of cell protein during logarithmic growth. Under similar conditions, *N. gruberi* amebae consume 80 ng atoms O per minute per mg of cell protein (Weik and John 1979b). The lower oxygen consumption, and presumably oxygen requirement, of *N. fowleri* probably explains the presence of the pathogen in heated waters in which dissolved oxygen concentrations are substantially reduced. The respiratory rate gradually declines during the stationary phase. The reduction in respiratory rate may involve respiratory control as increases in respiratory rate did not occur despite the addition of oxygen (Weik and John 1979a). The respiratory process of isolated *N. fowleri* mitochondria is similar to that of classic mammalian cell mitochondria. Oxidation is coupled to phosphorylation (adenosine triphosphate (ATP) formation) as shown by the two- to three-fold increase in respiration on addition of a phosphate acceptor or an uncoupling agent. The spectra of oxidized and dithionite-reduced mitochondria show distinct absorption bands of flavins and c-type, b-type and a-type cytochromes (Weik and John 1979a).

Genetics

It has generally been assumed that reproduction in *Acanthamoeba* and *Naegleria* is asexual and that sexuality, or genetic exchange, does not occur. In the past, genetic studies have been hampered because of difficulty in visualizing the very small, numerous chromosomes of these amebae, which may number 16 for *Naegleria* (De Jonckheere 1989) and 80 for *Acanthamoeba* (Volkonsky 1931). Fulton (1970) reported that one strain of *N. gruberi* had twice the ploidy of another strain, based on cell and nuclear volume and DNA content. Cariou and Pernin (1987) and Pernin et al. (1992) provided evidence for diploidy and genetic recombination in *N. lovaniensis*. De Jonckheere (1989) compared the electrophoretic karyotypes of all the species of *Naegleria* and concluded that, although karyotype analysis cannot be used to identify *Naegleria* species, it is useful for studying gene localization and genetic exchange. No genetic studies on the opportunistic amebae have been published. Clark and Cross (1987) described a self-replicating ribosomal DNA plasmid in *N. gruberi*, making it the third eukaryotic genus to have a nuclear plasmid DNA. Additionally, they sequenced the small-subunit rRNA gene of *N. gruberi* and showed that circular rRNA genes are a general feature of schizopyrenid (ameboflagellate) amebae, including, presumably, *N. fowleri* (Clark and Cross 1988).

CLINICAL ASPECTS

Clinical manifestations

PAM

PAM typically occurs in healthy children or young adults with a recent history of swimming in freshwater. The disease is rapidly fatal, usually resulting in death within 72 hours of the onset of symptoms. Infection follows entry of water containing amebae or flagellates into the nose. It has been suggested that inhalation of cysts (e.g. during dust storms) could lead to infection (Lawande et al. 1979). From the nasal mucosa, the amebae penetrate the cribriform plate and travel along the olfactory nerves to the brain. They invade the olfactory bulbs and then spread to the more posterior regions of the brain. Within the brain, the amebae provoke inflammation and cause extensive destruction of tissue (Carter 1970; Martinez 1985).

The clinical course is dramatic. Symptoms begin with severe frontal headache, fever (39–40°C) and anorexia followed by nausea, vomiting, and signs of meningeal irritation, frequently evidenced by a positive Kernig's sign. Involvement of the olfactory lobes may cause disturbances in smell or taste and may be noted early in the course of the disease. Visual disturbance may occur. The patient may experience confusion, irritability, and restlessness and may become irrational before lapsing into a coma. Generalized seizures may also occur. In order of frequency of occurrence, the more important symptoms are (Carter 1970; Martinez 1985):

- headache
- anorexia
- nausea
- vomiting
- fever
- neck stiffness.

GAE

GAE usually occurs in debilitated or chronically ill persons, some of whom may be undergoing immunosuppressive therapy. Infection by *Balamuthia* may occur in the immunocompetent. The underlying conditions reported in GAE are Hodgkin's disease, systemic lupus erythematosus, diabetes mellitus, glucose-6-phosphate dehydrogenase deficiency, alcoholism, and AIDS. Some of the victims of GAE are not debilitated or immunocompromised, but are otherwise healthy individuals. GAE is a disease not as well defined as that caused by *N. fowleri*. The course of infection is subacute or chronic, lasting weeks, months or even years, and is characterized by focal granulomatous lesions of the brain. The onset of GAE, unlike that of PAM, is insidious with a prolonged clinical course (Carter et al. 1981; Martinez 1987).

Acanthamoeba infection probably occurs through the lower respiratory tract or through ulcers of the skin or mucosa. Invasion into the CNS is by hematogenous spread from the primary focus of infection. As there are no lymphatic channels in the brain, invasion of the brain must be via the bloodstream (Martinez 1987). Even though some *Acanthamoeba* isolates are able to produce a CNS infection after intranasal instillation in mice, there is no proof that similar invasion occurs in the human disease. The portal of entry and spread in *Balamuthia* infection is believed to be the same as that for *Acanthamoeba*. The incubation period is not known, but probably lasts weeks or months and, during the prolonged clinical course, single or multiple space-occupying lesions develop. An altered mental state is a prominent feature in GAE. Headache, seizures, and neck stiffness occur in about half of the cases. Nausea and vomiting may also be noted (Martinez 1987).

ACANTHAMOEBA KERATITIS

Acanthamoeba keratitis is a chronic infection of the cornea caused by several species of *Acanthamoeba* including *A. castellanii*, *A. culbertsoni*, *A. hatchetti*, *A. polyphaga*, and *A. rhysodes* and infections are being diagnosed with increasing frequency (Stehr-Green et al. 1989). Infection is by direct contact of the cornea with amebae, which may be introduced through minor

corneal trauma or by exposure to contaminated water or contact lenses. The wearing of contact lenses and the use of home-made saline solutions are important risk factors. Saline solutions contaminated with protein residues from contact lenses promote the growth of bacteria and yeast which, in turn, are a source of food for the amebae. Amebae attach to the contact lenses stored in contaminated solutions and are transferred to the eye when lenses are placed over the cornea. Amebae become established as part of the conjunctival flora and may invade the corneal stroma through a break in the epithelium or through the intact epithelium. They produce an infection that progresses to *Acanthamoeba* keratitis, which usually develops over a period of weeks to months, and is characterized by:

- severe ocular pain (often out of proportion to the degree of inflammation)
- affected vision
- a stromal infiltrate that is frequently ring-shaped and composed predominantly of neutrophils.

Acanthamoeba keratitis is a serious ocular infection which, if not properly managed, can lead to loss of vision and even loss of the eye.

IMMUNOLOGY

The factors responsible for susceptibility and innate resistance to infection by pathogenic free-living amebae are undefined. Relatively few human infections have occurred, even though large numbers of individuals must have been exposed to amebae. Most cases of PAM occur in otherwise healthy children or young adults. *Acanthamoeba* keratitis also generally occurs in healthy individuals. In contrast, GAE usually occurs in persons who are chronically ill, debilitated or immunosuppressed, although *Balamuthia* infections may occur in the immunocompetent.

Antibodies to opportunistic amebae have been detected in human sera and include agglutinating antibodies against pathogenic and nonpathogenic *Naegleria* (Marciano-Cabral et al. 1987; Reilly et al. 1983). The agglutinating activity was specific for each species, indicating exposure to each of the *Naegleria* species. Antibodies to both pathogenic and nonpathogenic *Acanthamoeba* and *Naegleria* were detected in normal human sera by indirect fluorescent antibody testing of 93 serum samples. All were positive, with titers ranging from 1:5 to 1:80 (Cursons et al. 1980). An avidin-biotin horseradish peroxidase assay has been used to detect antibodies to pathogenic and nonpathogenic *Naegleria* in samples of human serum (Dubray et al. 1987). Antibodies were detected in 88 percent of sera from 115 hospital patients. Antibodies were identified as immunoglobulin (Ig)G and IgM, with IgG antibody titers ranging from 1:20 to 1:640. Radioimmunoassay detected antibody to *N. fowleri* in a pool of normal human sera (Tew et al. 1977). Antibody titers were nearly nine times greater against intracellular antigens than against cell surface antigens. The apparent widespread occurrence of antibodies to pathogenic free-living amebae in human sera may reflect the global distribution of these organisms. Alternatively, it may represent cross-reacting antibodies to antigens that have yet to be identified.

Serum from a victim of PAM in New Zealand was reported to have a low level of serum IgA, although IgG and IgM levels were normal (Cursons et al. 1979). In contrast, normal serum levels of IgA were found in a child who died of naeglerial infection in England (Cain et al. 1979). Because serum IgA levels may not be an accurate reflection of secretory IgA concentrations, both patients may have had deficient levels of secretory IgA. As *N. fowleri* invades the nasal mucosa, it seems reasonable to suggest that secretory IgA may play a role in protection. Except for the serological surveys described above, all other information on immune responses to pathogenic free-living amebae has come from experimental laboratory studies, mostly with animals (reviewed by John 1993).

PATHOLOGY

Pathogenicity

Pathogenicity is the ability of a microorganism to produce disease, whereas cytopathogenicity is the ability to produce pathologic change in cells or a cytopathic effect in vitro in cultured cells. The proposed mechanisms of cytopathogenicity for *N. fowleri* include phagocytosis, release of cytolytic substances and the presence of a biologically active component, *Naegleria* ameba cytopathogenic material (NACM).

Phagocytosis is a basic function of amebae. It causes the destruction of cells, whether in cell culture or in human tissue and is, therefore, intimately involved in pathogenesis. Brown (1979) called the piecemeal engulfment of mouse embryo cells by *N. fowleri* trogocytosis (from the Greek for 'to nibble'). It is now known that trogocytosis is accomplished by amebostomes (John et al. 1985) that the amebae use to engulf particles of various sizes, including cultivated mammalian cells. In addition to phagocytosis and trogocytosis, *N. fowleri* seems to injure cultivated mammalian cells by another contact-mediated means. Marciano-Cabral et al. (1990) reported cytolytic factors on the membranes of amebae that lyse B103 rat nerve cells on contact. Lysis is followed by engulfment of cellular debris. Cytopathic activity was enhanced by the divalent cations calcium or magnesium.

Various phospholipases (phospholipase A, lysophospholipase, sphingomyelinase) have been identified in culture media in which *N. fowleri* is grown (Cursons et al. 1978; Hysmith and Franson 1982). The phospholipase activities from cultures of pathogenic *Naegleria* are

much greater than from cultures of nonpathogenic *Naegleria*. Phospholipases have also been reported to be present in media in which *A. culbertsoni* is grown. The amounts are greater in pathogenic *A. culbertsoni* cultures than in those of nonpathogenic *A. castellanii* (Cursons et al. 1978). Other enzymes, some with a possible role in pathogenesis, occur in *N. fowleri* extracts. These are various hydrolases, including acid phosphatase, several glycosidases, and elastase.

A cytopathic effect has been attributed to NACM, obtained from lysed amebae (Dunnebacke and Dixon 1989). NACM is isolated from lysates of *Naegleria* by centrifugation, filtration, and lyophilization and has been obtained from *N. fowleri*, *N. gruberi*, and *N. jadini*, but not from *Acanthamoeba*. NACM kills cells of a variety of avian and mammalian cell lines. After cultures are inoculated, there is a long latent period (4–10 days) followed by a short period (under 24 hours) during which the monolayer is destroyed. The cytopathic effect has been maintained in cell cultures through nine serial passages. NACM is a protein with a molecular mass of 36 000 kDa and an isoelectric point of pH 4.2. Monoclonal antibodies to NACM prevent its cytopathic activity. Fluorescent staining shows NACM to be located at the tips of the ameba's pseudopodia and in the peripheral cytoplasm. It forms ring-shaped structures resembling amebostomes (Dunnebacke and Dixon 1989).

PAM

The gross pathologic findings in PAM are remarkably constant. The cerebral hemispheres are usually edematous and swollen, meninges are diffusely hyperemic with a slight purulent exudate and the cortex contains many focal superficial hemorrhages. There is severe involvement of the olfactory bulbs, with hemorrhage, necrosis, and purulent exudate (Carter 1972; Martinez 1985).

Microscopic examination reveals many amebae in the subarachnoid and perivascular spaces. Presumably, the perivascular spaces provide a path of migration for the amebae, and the blood vessels supply the oxygen needed by these aerobic organisms. Small numbers of amebae are found clustered within the brain tissue and in the purulent exudate of the meninges and brain substance. Within the exudate, some amebae may be seen engulfed by macrophages. Many amebae contain phagocytosed cellular debris and erythrocytes. The purulent exudate contains numerous polymorphonuclear and mononuclear leukocytes (Carter 1972; Martinez 1985). Figure 9 shows *N. fowleri* amebae with engulfed erythrocytes in brain tissue; cysts do not occur in tissue.

The cortical gray matter is a preferred site for the ameba's development. Consequently, severe involvement occurs in the cerebral hemispheres, cerebellum, brain stem, and upper portions of the spinal cord. Encephalitis may be a result of light amebic invasion and inflammation or massive invasion with purulent, hemorrhagic necrosis. Typically, the olfactory bulbs are extensively invaded, with hemorrhage and an inflammatory exudate; the involvement here is greater than in other areas of the brain. Infection of the central nervous system with *N. fowleri* may be described best as an acute, hemorrhagic, necrotizing meningoencephalitis (Carter 1972; Martinez 1985). Focal demyelination in the white matter of the brain and spinal cord may occur (Chang 1979; Duma et al. 1971). Curiously, demyelination may occur in the absence of amebae or cellular infiltrate. Chang (1979) suggests that demyelination may be caused by a phospholipolytic enzyme or enzyme-like substance produced by actively growing amebae present in the adjacent gray matter.

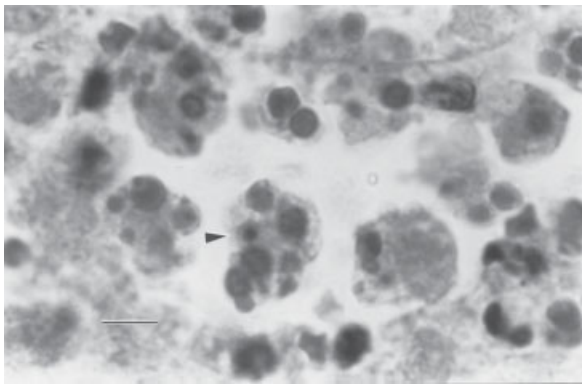

Figure 9 *Histological section of brain with* Naegleria fowleri *amebae containing engulfed erythrocytes (H&E stain). Prominent nucleolus visible within nucleus of one ameba (arrowhead). Bar = 10 μm*

GAE

In contrast to naeglerial infection, which is characterized by a diffuse meningoencephalitis, *Acanthamoeba* and *Balamuthia* CNS disease is a focal granulomatous encephalitis. Martinez (1980) gave a summary of the neuropathological features for 15 patients with GAE. In affected areas, the leptomeninges contain a moderate amount of purulent exudate. The cerebral hemispheres show moderate or severe edema with foci of softened tissue and associated hemorrhagic necrosis. Lesions are usually multifocal and more posterior, including the upper portion of the spinal cord. The olfactory bulbs are not usually involved. Lesions of the CNS in GAE are characterized by necrosis with hemorrhagic foci and localized leptomeningitis. The chronic inflammatory exudate over the cortex comprises mostly mononuclear cells with a few polymorphonuclear leukocytes. The brain substance may have a prominent granulomatous reaction with foreign-body giant cells, which are never seen in naeglerial infection. The multinucleated giant cells may not be present in immunosuppressed patients (Carter et al. 1981; Martinez 1987).

Amebae reach the brain via the bloodstream, invasion of the CNS is thus centrifugal, from the deeper tissues

toward the brain surface. Trophozoites and cysts (Figures 10 and 11) occur in most infected tissues and around blood vessels. *Acanthamoeba* and *Balamuthia* reach the CNS by hematogenous spread from a primary focus of infection elsewhere in the body, most probably the skin, mucosa or lungs. Within the infected primary tissues, there occurs a chronic granulomatous reaction like that seen in the brain, with multinucleated giant cells, trophozoites, and cysts. Similar lesions have been described from other tissues including prostate, thyroid, uterus, and pancreas, probably resulting from hematogenous dissemination of amebae from the primary focus in the skin or lungs, or possibly even a secondary CNS lesion (Martinez 1987).

ACANTHAMOEBA KERATITIS

Ocular infections with *Acanthamoeba* are characterized by chronic progressive ulcerative keratitis (Cohen et al. 1985). During early corneal infection, there may be pseudodendritic figures in the epithelium or just beneath the epithelium in the anterior stroma (Johns et al. 1987). In advanced cases of *Acanthamoeba* keratitis, there may be a marked stromal infiltrate and necrosis. The whitish inflammatory infiltrate, often appearing ring-shaped around the corneal ulcer, consists mainly of polymorphonuclear leukocytes and macrophages, with a few lymphocytes (Mathers et al. 1987). Although granulomatous inflammation has been described in *Acanthamoeba* keratitis, in most of the reports, neutrophils (not lymphocytes) are the predominant infiltrating cells. Corneal ulceration may progress to perforation (Lindquist et al. 1988).

DIAGNOSIS

Laboratory diagnosis

The laboratory diagnosis of infection by the opportunistic amebae depends on the recovery and identification of amebae in cerebrospinal fluid (CSF), brain tissue or corneal scrapings. Amebae in a clinical specimen may also be cultivated on non-nutrient agar spread with gram-negative bacteria and later transferred to liquid medium with antibiotics for axenic growth.

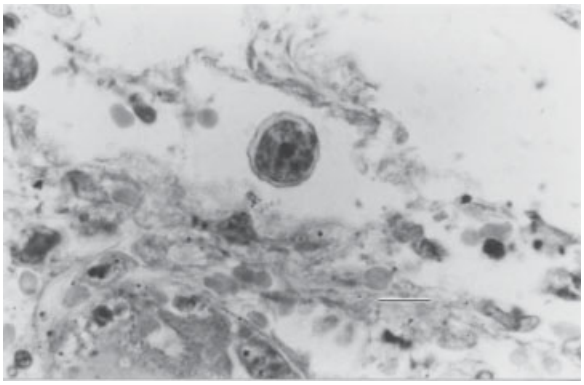

Figure 11 *Histological section of brain with* Acanthamoeba castellanii *cyst exhibiting typical wrinkled ectocyst (H&E stain). Bar = 10 μm*

PAM

The diagnosis of PAM is made by microscopic identification of living or stained amebae in CSF; motile amebae are readily seen in simple wet-mount preparations. Amebae can be distinguished from other cells by their limax shape and progressive movement. It is not necessary to warm the slide as amebae remain fully active at room temperature. Refrigeration of the spinal fluid is not recommended because this may kill the amebae.

Spinal fluid smears may be stained with Wright or Giemsa stains. The bacterial Gram stain is of little value because heat fixing destroys the amebae, which causes them to stain poorly and appear as degenerating cells. Giemsa- or Wright-stained amebae have considerable amounts of sky-blue cytoplasm and relatively small, delicate, pink nuclei. Mononuclear leukocytes, on the other hand, have large purplish nuclei with only a small amount of sky-blue cytoplasm. In cytospin preparations of CSF, the amebae tend to be rounded and flattened, without pseudopodia. Occasionally, enlarged teardrop-shaped food vacuoles appear to radiate from the nucleus but this is an artefact induced by the cytospin procedure (Benson et al. 1985). Amebae may be cultivated by placing some of the CSF on non-nutrient agar (1.5 percent) spread with a lawn of washed *Escherichia coli* or *Enterobacter aerogenes* and incubated at 37°C. The amebae grow on the moist agar surface and use the bacteria as food, producing plaques as they clear the bacteria.

Clinically, PAM closely resembles fulminating bacterial meningitis, and the laboratory findings are also similar. The CSF is purulent or sanguinopurulent, with leukocyte counts (predominantly neutrophils) ranging from a few hundred to more than 20 000 cells mm^{-3}.

Spinal fluid glucose levels are low and protein content is generally increased. Typically, Gram-stained smears and cultures of spinal fluid are negative for bacteria (Carter 1972; Martinez 1985).

GAE

The laboratory diagnosis of GAE is made by identifying amebic forms of *Acanthamoeba* or *Balamuthia* in the CSF, or amebae and cysts in brain tissue. Whereas *N. fowleri* is readily cultured from CSF, *Acanthamoeba* and *Balamuthia* are not. *Acanthamoeba* has only rarely been isolated from patients with GAE. *A. culbertsoni* and *A. rhysodes* have been cultured from CSF, and *Acanthamoeba* sp. and *A. palestinensis* have been cultured from aspirated and biopsied brain material, respectively. Leptomyxid amebae have been cultivated twice from biopsy material (Visvesvara et al. 1990; Gordon et al. 1992).

As with *N. fowleri*, *Acanthamoeba* may be cultured on non-nutrient agar spread with washed *E. coli* or *E. aerogenes*. *Balamuthia* must be grown in tissue culture, preferably Vero cell (Visvesvara et al. 1993). *Acanthamoeba* and *Balamuthia* do not have a flagellate stage but amebae are identified by their small spiky acanthopodia or branching shape, respectively, and cysts are readily identified by their distinctive double-walled wrinkled appearance. Species identification may be made by using the indirect fluorescent antibody technique (IFAT) and specific antisera against *Acanthamoeba* spp. or *B. mandrillaris*. The species of *Acanthamoeba* identified most frequently from cases of GAE have been *A. castellanii* and *A. culbertsoni*.

ACANTHAMOEBA KERATITIS

Acanthamoeba keratitis is diagnosed by identifying amebae cultured from corneal scrapings or by histological examination of infected corneal tissue. As in GAE, *Acanthamoeba* may be cultured from corneal scrapings on non-nutrient agar spread with gram-negative bacteria. Cultures of corneal material should be incubated at 30°C rather than 37°C. Of the five species of *Acanthamoeba* identified as capable of causing eye infections, only *A. hatchetti* has not been cultured from clinical material. Species identification is based on indirect immunofluorescent antibody staining. The two species most frequently identified in *Acanthamoeba* keratitis have been *A. castellanii* and *A. polyphaga*. *A. castellanii* is the species that has most often been identified in cases of *Acanthamoeba* GAE and ocular infection.

Rapid diagnosis of *Acanthamoeba* keratitis may be made by identifying amebae or cysts in corneal scrapings using procedures for Giemsa staining, calcofluor white staining (Wilhelmus et al. 1986), and IFAT (Epstein et al. 1986). The calcofluor white procedure and IFAT both require the use of fluorescence microscopy and IFAT also requires an antiserum to *Acanthamoeba*.

Histopathological preparations of corneal tissue may be stained using the conventional hematoxylin and eosin (H&E) procedure or by the more specialized staining procedures of Heidenhain's hematoxylin, Gomori's chromium hematoxylin, periodic acid–Schiff, Bauer chromic acid-Schiff, and silver methenamine (McClellan et al. 1988). The special staining techniques are useful for demonstrating the presence of cysts in corneal tissue. IFAT and calcofluor white staining also may be used (Silvany et al. 1987).

Herpes simplex keratitis is the disease most commonly mistaken for *Acanthamoeba* keratitis (Johns et al. 1987; Mannis et al. 1986; Moore and McCulley 1989). The single most consistent clinical symptom of *Acanthamoeba* keratitis is severe ocular pain, which is not characteristic of an infection limited to the cornea and generally not present in persons with herpes simplex keratitis. Additional distinguishing features of *Acanthamoeba* keratitis include a history of direct exposure to soil or water, wearing contact lenses, scleritis and failure of cultures from the inflamed eye to reveal bacteria, fungi or viruses (Mannis et al. 1986).

EPIDEMIOLOGY

Literature review

Human infection by *Naegleria* and *Acanthamoeba* has been reported worldwide, as has the environmental isolation of these opportunistic amebae (reviewed by John 1993). Although leptomyxid amebae have been identified as a cause of human disease (Visvesvara et al. 1990; Lowichik et al. 1995) and have been cultivated twice from tissue (Visvesvara et al. 1990; Gordon et al. 1992), the environmental isolation of pathogenic leptomyxid amebae has been reported only once (John and Howard 1995).

PAM

Most of the reports of PAM have been from the developed rather than the developing nations, probably because of greater awareness rather than greater incidence. Australia, Czechoslovakia, and the USA have reported 75 percent of all cases of PAM. In the USA, most reported cases have been from the coastal states of Virginia, Florida, and Texas, accounting for 67 percent of the cases.

The majority of patients with naeglerial infection have had a history of recent swimming in freshwater during hot summer weather. In Richmond, Virginia, infection in 14 of 16 cases was probably acquired in two man-made lakes located within a few miles of each other (Callicott Jnr 1968; Duma et al. 1971; dos Santos 1970). Over a 3-year period, 16 young people died in Czechoslovakia after swimming in the same heated and chlorinated

indoor swimming pool (Červa et al. 1968). Similar fatal cases have been reported following swimming in:

- swimming pools in Belgium, England, and New Zealand
- hot springs in California and New Zealand
- lakes in Arkansas, Florida, Missouri, Nevada, South Carolina, and Texas
- streams in Belgium, Mississippi, and New Zealand
- an irrigation ditch in Mexico.

Individual references for the above cases may be found in John (1993).

Infection has not always been acquired by swimming. The South Australian and northern Nigerian cases occurred in arid regions where swimming is unusual; the proposed means of infection were bathing and face washing (Anderson and Jamieson 1972; Lawande et al. 1980) or inhalation of dust-borne cysts (Lawande et al. 1979).

N. fowleri has been isolated from a variety of environmental sources in Africa, Asia, Australia, New Zealand, Europe, and North and South America, with 33 references describing 211 isolates (for specific references, see John 1993; John and Howard 1995). *N. fowleri* is more readily isolated from warm, clean water than from warm, organically enriched water. The average water temperature has been c. 30°C (range 15–45°C). Although laboratory animals may succumb to naeglerial infection, there is no evidence for an animal reservoir of *N. fowleri*.

GAE

There have been even fewer cases of *Acanthamoeba* CNS infection than of *Naegleria* infection. More than half of these have been reported from the USA. Unlike naeglerial infection, GAE is not associated with swimming. Infections often occur in persons who are debilitated or immunosuppressed including patients with acquired immunodeficiency syndrome (AIDS). In one of the AIDS patients, the clinical features were more like those of PAM than of GAE, presumably because of immunosuppression (Wiley et al. 1987). With the current increase in the number of immunosuppressed persons, it is likely that there will be a corresponding increase in disseminated *Acanthamoeba* infections.

GAE caused by the leptomyxid, *B. mandrillaris*, was first described in a pregnant mandrill baboon that died of meningoencephalitis at the San Diego Zoo (Visvesvara et al. 1990). Amebae were cultivated from brain tissue and used to prepare immune serum for indirect immunofluorescence assays; these revealed 16 human cases of leptomyxid infection originally identified as *Acanthamoeba* infections. Leptomyxid infections were also identified in a sheep, a horse, and a gorilla. Since the original description, leptomyxid infections continue to be reported in immunocompetent and immunosuppressed humans, including patients with AIDS.

At the time of writing, the world literature contains 26 references that describe the environmental isolation of 144 pathogenic *Acanthamoeba* isolates (for specific references see John 1993; John and Howard 1995). These have been recovered from a variety of sources at somewhat lower average temperatures than for the isolation of *N. fowleri* (below 25°C). Only one report describes the environmental recovery of pathogenic leptomyxid isolates and these do not appear to be *Balamuthia* (John and Howard 1995). As with *N. fowleri*, there is no evidence for an animal reservoir of pathogenic *Acanthamoeba* or *Balamuthia*.

ACANTHAMOEBA KERATITIS

The first cases of *Acanthamoeba* keratitis were reported from the UK in 1974 (Nagington and Watson 1974) and the USA in 1975 (Jones et al. 1975) and were associated with trauma to the eye or exposure to contaminated water. Since 1985, there has been a dramatic increase in the number of cases associated with the wearing of contact lenses; the greatest increase occurred in wearers of soft contact lenses (Stehr-Green et al. 1989). The continued increase in the number of contact lens wearers, and of those not properly caring for their lenses, will undoubtedly result in an increase in the incidence of *Acanthamoeba* keratitis, mainly in the developed nations where the wearing of contact lenses is widespread.

CHEMOTHERAPY

Overview

Although *Acanthamoeba* keratitis may be treated with antimicrobial agents, virtually all cases of PAM and GAE have been fatal because there is no effective treatment.

PAM

At present, there is no satisfactory treatment for PAM. The antibiotics used to treat bacterial meningitis are ineffective in naeglerial infection, as are the antiamebic drugs. Amphotericin B, a drug of considerable toxicity, is the antinaeglerial agent for which there is evidence of clinical effectiveness. The four known survivors of PAM, children from Australia (Anderson and Jamieson 1972), the UK (Apley et al. 1970), India (Pan and Ghosh 1971), and the USA (Seidel et al. 1982), were treated with amphotericin B, given intravenously and intrathecally. The patient in the USA was also given parenteral miconazole and oral rifampicin (Seidel et al. 1982). In experimental infections, tetracycline acts synergistically with amphotericin B to protect mice (Thong et al. 1979). Goswick and Brenner (2003) describe the effective treatment of experimental PAM in mice with azithromycin. Treatment was initiated 72 hours after infection and was

continued for 5 days, with protection being 100 percent and greater than for amphotericin B-treated mice. Interestingly, the patient who recovered from *Sappinia diploidea* encephalitis also was treated with azithromycin (Gelman et al. 2001).

Amphotericin B is administered intravenously at high doses; 1–15 mg/kg of body weight daily for 3 days and then 1 mg/kg per day for 6 days. Additionally, amphotericin B may be given intrathecally and miconazole is administered intravenously (Carter 1972; Seidel et al. 1982). Amphotericin B is a polyene compound that acts on the plasma membrane, disrupting its selective permeability and causing leakage of cellular components. On exposure to amphotericin B, amebae round up and fail to form pseudopodia. Membrane-related changes, evident by electron microscopy, include enhanced nuclear plasticity, increased amounts of smooth and rough endoplasmic reticulum, decreased food vacuole formation and production of blebs on the plasma membrane (Schuster and Rechthand 1975).

GAE

As with naeglerial infection, there is no satisfactory treatment for GAE, partly because most cases have been diagnosed after death and there has not been adequate opportunity to evaluate therapeutic regimens. There are three reports of persons having recovered from *Acanthamoeba* CNS infection. A 7-year-old girl with a single *Acanthamoeba*-induced granulomatous brain tumor recovered following total excision of the mass and treatment with ketoconazole. *A. palestinensis* was cultured from the brain biopsy material (Ofori-Kwakye et al. 1986). The second report involved a 40-year-old man with *Acanthamoeba* meningitis who recovered following treatment with penicillin and chloramphenicol. *A. culbertsoni* was repeatedly cultured from the patient's CSF (Lalitha et al. 1985). The third case, for whom complete recovery cannot be claimed because the patient returned home and was not followed-up, was a 30-year-old man with chronic meningoencephalitis who was treated with sulfamethazine and from whose CSF *A. rhysodes* was cultured (Cleland et al. 1982).

Because the cysts of *Acanthamoeba* and *Balamuthia* form in tissues, a potentially effective drug for GAE must be able to destroy cysts as well as amebae. Otherwise, a possible relapse could occur after the course of treatment has ended.

ACANTHAMOEBA KERATITIS

Most of the earlier cases of *Acanthamoeba* keratitis required corneal transplants in order to manage the disease. Even so, there were reported instances of surgical enucleation. With present therapies, *Acanthamoeba* keratitis can be managed by medical treatment alone if infection is identified soon enough (Moore and McCulley 1989). The first successful medical cure of *Acanthamoeba* keratitis was reported by Wright et al. (1985) and involved the use of a combination of dibromopropamidine and propamidine isethionate ointment and drops and neomycin drops. The success of this treatment has been confirmed by others. Signs of toxicity of propamidine and dibromopropamidine have been reported in one patient (Yeoh et al. 1987), but when treatment was discontinued, there seemed to be a recurrence of the *Acanthamoeba* keratitis.

In addition to topical propamidine, other successful treatment regimens have used:

- topical miconazole and systemic ketoconazole (Wilhelmus et al. 1986)
- topical miconazole and neosporin with epithelial debridement (Lindquist et al. 1988)
- topical clotrimazole (Driebe Jnr et al. 1988)
- oral itraconazole with topical miconazole and surgical debridement (Ishibashi et al. 1990)
- topical polyhexamethylene biguanide (Larkin et al. 1992).

PREVENTION AND CONTROL

Vaccination

There is no vaccine to protect against infection by the opportunistic amebae. Numerous attempts have been made to immunize mice against infection by *N. fowleri* or *Acanthamoeba*, without producing solid immunity (for details of the studies, see John (1993)).

Integrated control

Because of the relationship of swimming to naeglerial infection, many swimming areas have been subjected to intense investigation. Although *N. fowleri* has been isolated from many such areas, not all sampling efforts have yielded *N. fowleri*. Obviously, there are factors that favor the development of *N. fowleri* in swimming areas, including a warm temperature, the presence of an adequate food supply, insufficient residual free chlorine, minimal competition from other protozoans and probably optimal pH and oxygen levels. With the present limited understanding of the ecology of *N. fowleri*, practical measures for the prevention and control of the infection include education of the public, awareness within the medical community and adequate chlorination of public water supplies, including swimming facilities. Adequate chlorination requires a continuous free residual chlorine level of 0.5 mg per liter of water (Derreumaux et al. 1974) and remains the single most effective disinfectant system for controlling opportunistic amebae in public waters. This level of chlorination has effectively controlled the *N. fowleri* problem in the public water supplies of South Australia (Dorsch et al. 1983). The risk of acquiring naeglerial infection through

swimming in Florida's freshwater lakes is estimated at c. 1 in 2.6 million exposures (Wellings 1977). Considering the millions of persons who swim outdoors each summer, it is truly remarkable that there are not more cases of PAM.

Factors that have been associated with *Acanthamoeba* keratitis in contact lens wearers are:

- using nonsterile, home-made saline
- disinfecting lenses less frequently than recommended
- wearing lenses while swimming (Stehr-Green et al. 1987).

Contact lens wearers should closely follow the manufacturer's recommendations for wear, care, and disinfection of lenses. Home-made saline solutions remain an important risk factor associated with *Acanthamoeba* keratitis. Contamination of the contact lens care system with bacteria or fungi encourages the survival and growth of *Acanthamoeba*. Amebae, including *A. polyphaga* and *A. hatchetti*, have been isolated from laboratory eyewash stations, especially stations containing reservoirs (Bier and Sawyer 1990; Tyndall et al. 1987). Eyewash stations with reservoirs should be flushed weekly, otherwise they potentially present a health hazard to users, particularly those wearing contact lenses.

With the expected increase in the number of contact lens wearers, there will undoubtedly be a corresponding increase in the number of cases of *Acanthamoeba* keratitis. As immunosuppression becomes more widespread (not just because of AIDS but also because of organ transplantation, cancer chemotherapy, congenitally acquired immunodeficiency, and suppression resulting from the indiscriminate release of toxic chemicals and carcinogens into the environment), the possibility of more CNS and disseminated *Acanthamoeba* infections also increases.

INTRODUCTION

Giardia was first seen by Leeuwenhoek in his own stool specimens in 1681, but was not described until 1859 by Lambl. In the early 1930s, Clifford Dobell translated a number of Leeuwenhoek's works from Dutch and Latin. In the account of his own giardiasis infection, Leeuwenhoek writes (Dobell 1920):

> All the particles aforesaid (description of stool debris) lay in a clear transparent medium, wherein I have sometimes also seen animalcules a-moving very prettily (trophozoites); some of 'em a bit bigger, others a bit less, than a blood-globule, but all of one and the same make. Their bodies were somewhat longer than broad, and their belly which was flatlike, furnisht with sundry little paws, wherewith they made such a stir in the clear medium and among the globules, that you might e'en fancy you saw a pissabed (woodlouse or sow-bug) running up against a wall; and albeit they made a quick motion with their paws, yet for all that they made but slow progress.

However, there is no evidence that either Leeuwenhoek or Lambl saw or recognized the cyst forms of the organism; they were first noted by Grassi in 1879 and were thought to be coccidia. Only later did Grassi associate the cyst form with the flagellated trophozoite form (Meyer 1990). The history of giardiasis is given in History of human parasitology.

Giardia lamblia is worldwide in distribution, apparently more prevalent in children than in adults, and more common in warm climates than in cool ones. It is the most commonly diagnosed flagellate in the intestinal tract, and it may be the most commonly diagnosed intestinal protozoan in some areas of the world with an estimated 2.8×10^8 cases per year (Lane and Lloyd 2002).

CLASSIFICATION

Although various criteria have been used to differentiate species of *Giardia*, including host specificity, various body dimensions, and variations in structure, there is still considerable debate over the appropriate classification and nomenclature of this group of organisms. Based on work by Filice (1952) on structural variations, three groups have been proposed: amphibian *Giardia* (represented by *G. agilis*), the muris group from rodents and birds (represented by *G. muris*), and the intestinalis group from a variety of mammals (including humans), as well as birds and reptiles (represented by *G. duodenalis*). Despite disagreement concerning the names *intestinalis* and *lamblia*, both continue to be used to describe this organism. Meyer prefers to use *Giardia duodenalis*, which is often followed by the name of the animal from which the organism was obtained (Meyer 1990).

Ten strains from human- and animal-source *G. duodenalis* were evaluated using an isoelectric focusing technique. Banding patterns obtained from trophozoite total cell proteins demonstrated both similarities and differences. These findings confirm the heterogeneity of this group of *Giardia* spp., from animal and human hosts and from hosts within the same geographical area (Isaac-Renton et al. 1988; Ey et al. 1996; McIntyre et al. 2000; Monis et al. 1999; Sulaiman et al. 2003, 2004).

In a recent study from Australia, ribosomal RNA sequencing revealed differences between the genotypes of *Giardia* isolates recovered from humans and dogs living in the same locality. Results from the study suggest that zoonotic transmission of *Giardia* infections between humans and dogs does not occur frequently in the particular communities studied. The dog-associated sequences have not been reported before, suggesting that there may be a new *G. duodenalis* subgroup (Hopkins et al. 1997). However, in a recent study in India, *G. duodenalis* isolates recovered from humans and dogs living in the same locality were characterized at three different loci; the SSU-rDNA, elongation factor 1-alpha (ef1-α), and triose phosphate isomerase (*tpi*) gene. Analysis of the *tpi* gene placed canine *Giardia* isolates within the genetic groupings of human isolates (Assemblages A and B). Epidemiological data showing a highly significant association between the prevalence of *Giardia* in humans and the presence of a *Giardia*-positive dog in the same household provided further evidence for zoonotic transmission (Traub et al. 2004).

Molecular classification tools have been very valuable in delineating the pathogenesis and host range of *Giardia* isolates obtained from humans and a variety of other mammals. Molecular typing indicates that most animal parasites are not infective to humans but those that are can be genotypically classified into assemblage A or B (Lane and Lloyd 2002). In one study, assemblage A isolates were solely detected in patients with intermittent diarrheal complaints, while assemblage B isolates were present in patients with persistent diarrheal complaints (Homan and Mank 2001). Restriction fragment length polymorphism (RFLP) analysis has distinguished two groups (designated groups I and II) within assemblage A (Amar et al. 2002). Currently, assemblages A (groups 1 and 2), and B (groups 3 and 4) contain human pathogens, while C through G are found in other mammals (Adam 2001). The phylogeny of the organism has not been finalized, but there is a growing opinion that *Giardia* may not be an ancient eukaryote, but that it may be derived from a more complex mitochondria-containing protozoan (Lane and Lloyd 2002).

Within the USA and other areas throughout the world, the term *Giardia lamblia* has been commonly used for many years and refers to those organisms found in humans, as well as other mammals. In some geographic areas, this designation tends to eliminate any confusion, since the majority of health workers are used to this name and continue to report the presence of the organism using it. Others feel the designation *G. duodenalis* is taxonomically correct and refers to the many 'species' containing the 'duodenalis' double medial bodies. As long as both laboratory staff and physicians use the same species designation, the choice is optional.

STRUCTURE AND LIFE CYCLE

The life cycle is illustrated in Figure 1 and is similar to the simple, direct life cycle of most intestinal protozoa. Both the trophozoite and cyst are included in the life cycle of *G. lamblia*. Trophozoites divide by means of longitudinal binary fission producing two daughter trophozoites. The trophozoites are the intestinal dwelling stages and attach to the epithelium of the host villi by means of the ventral disc. The attachment is substantial and results in disc impression prints when the organism detaches from the surface of the epithelium. Trophozoites may remain attached or may detach from the mucosal surface. Since the epithelial surface sloughs off the tip of the villus every 72 h, the trophozoites apparently detach at that time.

There are several theories on possible mechanisms for attachment by the ventral disk; they include microtubule mediation, hydrodynamic action, contractile protein activity, and the interaction of lectins with surface bound sugars. Based on conflicting information, the attachment process probably depends on multiple mechanisms. A study by Katelaris and colleagues indicates that attachment to enterocyte-like differentiated Caco-2 cells is primarily by cytoskeletal mechanisms that can be inhibited by interfering with contractile filaments and microtubules; attachment by mannose binding lectin also seems to mediate binding (Katelaris et al. 1995).

The most common location of the organisms is in the crypts within the duodenum. For reasons that are not known, cyst formation takes place as the organisms move down through the colon.

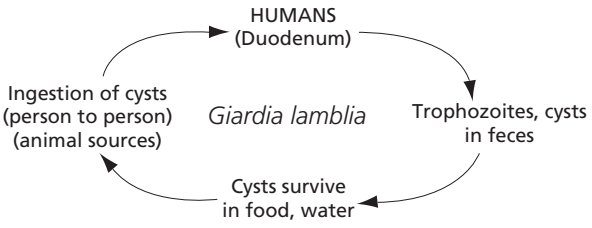

Figure 1 *Life cycle of* Giardia lamblia. *(Adapted from Garcia 2001)*

The *Giardia* encystation process can be divided into three parts:

1 stimulus for encystation
2 synthesis and intracellular transport of cyst wall components
3 assembly of the extracellular cyst wall.

It has been suggested that a cholesterol-regulated process similar to that in mammalian cells occurs during the induction of encystation in *Giardia*. The formation of the cyst wall during encystation is characterized by the appearance of dense encystation-specific vesicles (ESV). These ESVs transport cyst wall components to the plasma membrane of the encysting cell and release their contents to the cell exterior during cyst wall formation. Information also suggests that the cyst wall contains only two cyst proteins; these proteins appear to be common components of the cyst walls of a variety of intestinal parasitic protozoa.

The *Giardia* cyst wall is composed of an outer filamentous portion and an inner membranous portion. The process begins with the appearance of cyst wall antigens that appear on small protrusions of the trophozoite surface; these eventually form cap-like structures and may cover the entire surface of the trophozoite. Based on the filamentous nature of the cyst wall and its constant thickness, it may form from successive layers of cyst wall materials. The cyst wall has also been found to be somewhat flexible, but rigid enough to maintain its shape after the excysted trophozoite has left the cyst (Lujan et al. 1997).

Based on results by Halliday et al. (1995). *Giardia* appears to take up conjugated bile salts by active and passive transport mechanisms like the mammalian ileum. As conjugated bile salts are known to promote encystation, these uptake mechanisms may play an important role in the survival of the cyst stage and ultimate completion of the life cycle of the parasite (Das et al. 1997; Healy 1990). Cholesterol starvation may also play a role in stimulating encystation (Lujan et al. 1996). The trophozoites retract the flagella into the axonemes, the cytoplasm becomes condensed, and the cyst wall is secreted (Erlandsen et al. 1996). As the cyst matures, the internal structures are doubled so that when excystation occurs, the cytoplasm divides to produce two trophozoites. Excystation would normally occur in the duodenum or appropriate culture medium (Bingham and Meyer 1979). If kept cool and moist, cysts can remain viable for several months, but they cannot survive if moisture is lacking.

At the light microscopic level and seen on permanent stained fecal smears stained with trichrome or iron-hematoxylin stains, the trophozoite is usually described as teardrop-shaped from the front with the posterior end being pointed (Figures 2 and 3). Examined from the side, the trophozoite resembles the curved portion of a spoon. The concave portion is the area of the sucking disc (Figure 2). There are four pairs of flagella, two nuclei, two axonemes, and two slightly curved bodies called the median bodies. The trophozoites usually measure 10–20 μm in length and 5–15 μm in width (Figure 3 and Table 1)

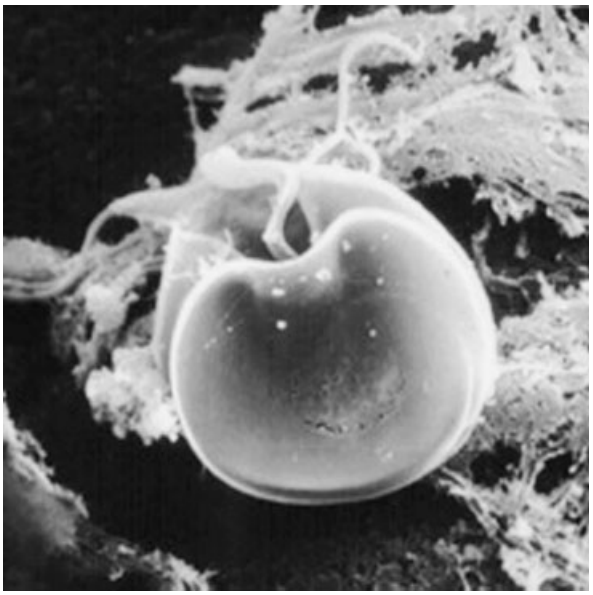

Figure 2 *Scanning electron micrograph of* Giardia lamblia *trophozoite on the mucosal surface. (Courtesy of Marietta Voge) (Garcia 2001)*

The cysts may be either round or oval and contain four nuclei, axonemes, and median bodies (Figure 3). Often, some cysts appear to be shrunk or distorted and one may see two halos, one around the cyst wall itself and one inside the cyst wall around the shrunken organism. The halo effect around the outside of the cyst is particularly visible on permanent stained smears. Cysts normally measure 11–14 μm in length and 7–10 μm in width (Figure 3 and Table 2).

BIOCHEMISTRY, MOLECULAR BIOLOGY, AND GENETICS

Organisms in the genus *Giardia* are described as aerotolerant anaerobes that use substrate-level phosphorylation, iron-sulfur protein- and flavoprotein-mediated electron transport for the production of energy (Jarroll and Lindmark 1990). *Giardia* lacks mitochondria and microbodies, but contains lysosome-like organelles that accumulate ferritin and stain positively for acid phosphatase and aryl sulfatase (Upcroft and Upcroft 1998).

In the presence of exogenous glucose, intact *Giardia* trophozoites produce ethanol and acetate as organic end-products: aerobically, six times more acetate than ethanol is produced; anaerobically, twice as much ethanol as acetate is produced. In both situations, carbon dioxide is the only gaseous end-product that has been detected. Based on the pattern of carbon dioxide

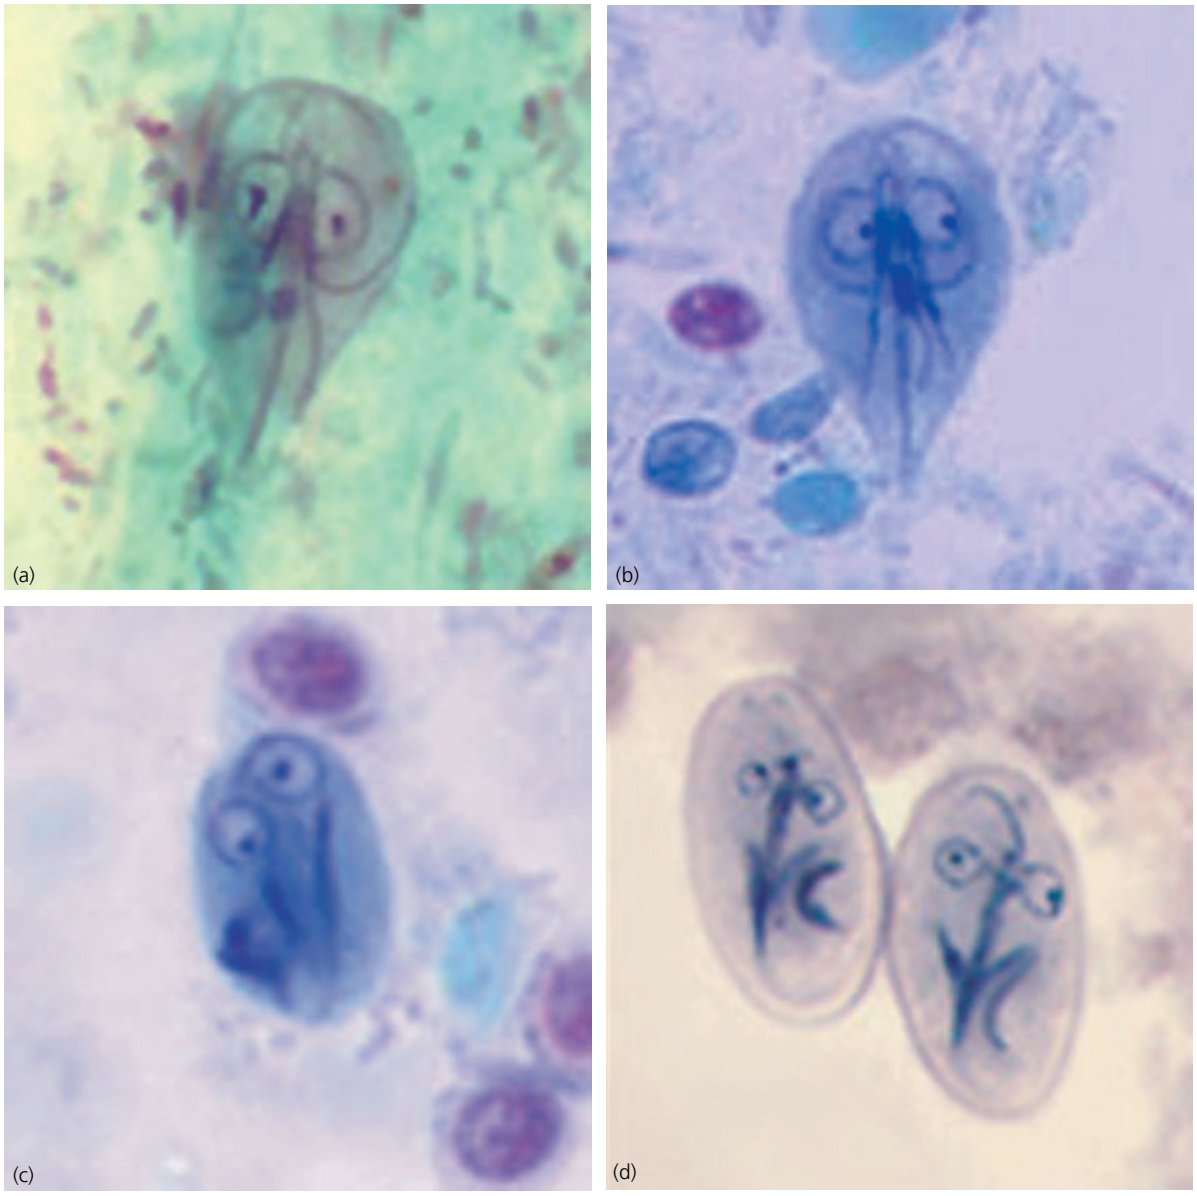

Figure 3 Giardia lamblia *(a, b) trophozoites stained with Wheatley's trichrome;* **(c)** *cyst stained with Wheatley's trichrome;* **(d)** *cysts stained with iron hematoxylin.*

production, glucose is metabolized using the Embden-Meyerhof-Parnas (EMP) pathway and the hexose monophosphate (HM) pathway. A number of energy metabolism enzymes have been identified and are reviewed by Jarroll and Lindmark (1990).

Carbohydrate and energy metabolism studies have also been conducted using the cyst stage; enzyme data confirm that specific activities occur regardless of the life-cycle stage involved. Studies also show that the cyst stage respires at c. 10–20 percent of the rate observed in trophozoites; respiration is not stimulated by exogenous glucose, but by exogenous ethanol. It is also interesting to note that cyst respiration decreases as water temperature decreases. These findings may explain increased cyst viability with decreased storage temperature.

In summary, a proposed energy metabolic pathway for *Giardia* indicates oxidation of endogenous and exogenous glucose incompletely to ethanol, acetate, and carbon dioxide. Energy is produced through substrate-level phosphorylation; iron-sulfur proteins and flavins are involved in electron transport. There is no evidence for oxidative phosphorylation or a cytochrome-mediated electron transport system (Jarroll and Lindmark 1990).

The fact that *Giardia* shares many metabolic attributes of the anaerobic bacteria provides a wide range of drug targets for future consideration. An example is the utilization of the amino acid arginine as an energy source, using the arginine dihydrolase pathway, which occurs in a number of anaerobic bacteria (Brown et al. 1998).

Table 1 Giardia lamblia *trophozoite morphology*

Organism stage	Shape and size	Motility	Nuclei	Flagella	Other features
Giardia lamblia trophozoite	Pear-shaped, 10–20 μm; width 5–15 μm	'Falling leaf' motility may be difficult to see if organism in mucus	Two nuclei Not visible in unstained mounts	Four lateral, two ventral, two caudal	Sucking disc occupying ½–¾ of ventral surface pear-shaped front view; spoon-shaped side view

Culture studies indicate that *Giardia* trophozoites have the capacity to synthesize isoprenoid lipids de novo, as well as to incorporate preformed lipids; also, steryl esters are abundant and increase during encystation, while triglycerides are low (Ellis et al. 1996; Gibson et al. 1999). The phospholipids present include phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, phosphatidylserine, and sphingomyelin. Neutral lipids present include sterols, mono-, di-, and triacylglycerides. Fatty acids can be incorporated into phospho- and neutral lipids (Jarroll and Lindmark 1990). Increased fatty acid unsaturation and the accumulation of storage lipids are consistent with the parasite differentiation into a cyst stage that can survive outside the host.

In the trophozoite, nucleic acid requirements are met by the salvage of pyrimidines, purines, and their nucleosides. Various carrier-mediated mechanisms have been proposed.

In contrast to trophozoites of *Entamoeba* and the trichomonads, *Giardia* has very few carbohydrate-splitting hydrolases. It has also been found that *Giardia* trophozoites exhibit increased levels of chitin synthetase activity during encystment (Jarroll and Lindmark 1990).

Although antigenic analysis shows promise in helping to identify and classify *Giardia*, both common and different antigens have been recovered in axenic cultures. The use of monoclonal antibodies in the study of antigens has proved useful; technical methods also involve quantitation, an important requirement in this type of analysis. Another potential problem involves antigenic variation; a single *Giardia* trophozoite can give rise in vivo, as well as in vitro, to trophozoites with varying surface antigens. Immune pressure may play a role in antigenic variation, but the speed with which antigenic changes take place after infection suggests that other mechanisms may also be involved. The antigenic profile of *Giardia* in culture may also change if the trophozoites harbor endosymbionts; the presence of these organisms may influence both antigenic and chemotaxonomic determinations (Meyer 1990).

Giardia lamblia is known to undergo surface antigenic variation. The antigens involved belong to a group of variant-specific surface proteins (VSP) that are unique cysteine-rich zinc finger proteins. Selection by immune-mediated processes is a possibility, especially because switching occurs at the same time that humoral responses are first detected. The purpose of antigenic variation may be the presentation of a wide variety of VSPs to the various hosts, increasing the chances of successful initial infection or reinfection (Nash 1997). Since VSPs are resistant to the effects of intestinal proteases, they may allow the organism to survive in the protease-rich small intestine (Nash 2002). Thus, the two major hypotheses concerning antigenic variation are evasion of the host immune system and allowing the parasites to survive in different intestinal environments; certainly these hypotheses are not mutually exclusive (Adam 2001).

CLINICAL ASPECTS

From available data, it appears the incubation time for giardiasis is c. 12–20 days. Because the acute stage usually lasts only a few days, giardiasis may not be recognized as the cause of the symptoms observed, which may mimic acute viral enteritis, bacillary dysentery, bacterial or other food poisonings, acute intestinal amebiasis or 'traveler's diarrhea' (toxigenic *E. coli*). However, the type of diarrhea plus the lack of blood, mucus, and cellular exudate is consistent with giardiasis.

Clinical manifestations

Nausea, anorexia, malaise, low-grade fever, and chills may accompany onset. There may be a sudden onset of

Table 2 Giardia lamblia *cyst morphology*

Organism stage	Shape and size	Motility	Nuclei	Flagella	Other features
Giardia lamblia cyst	Oval, ellipsoidal or may appear round 8–19 μm; usual range 11–14 μm; width, 7–10 μm	Nonmotile	Four nuclei – not distinct in unstained preparations; usually located at one end	Flagella not visible	Longitudinal fibers in cysts may be visible in unstained preparations; deep staining median bodies usually lie across the longitudinal fibers; there is often shrinkage and the cytoplasm pulls away from the cyst wall; there may also be a 'halo' effect around the outside of the cyst wall due to shrinkage caused by dehydrating reagents

explosive, watery, foul-smelling diarrhea with flatulence and abdominal distention. Other symptoms include epigastric pain and cramping. There is increased fat and mucus in the stool, but no blood. Weight loss often accompanies these symptoms. The acute infection usually resolves spontaneously, although in some patients, particularly children, the acute symptoms may last for months. Acute giardiasis must be differentiated from other acute viral, bacterial, and protozoal agents.

The acute phase is often followed by a subacute or chronic phase. Symptoms in these patients include recurrent, brief episodes of loose, foul stools; there may be increased distention and foul flatus. Between mushy stools, the patient may have normal stools or may be constipated. Abdominal discomfort continues to include marked distention and belching with a rotten egg taste. Chronic disease must be differentiated from amebiasis and other intestinal parasites such as *Dientamoeba fragilis*, *Cryptosporidium parvum*, *Cyclospora cayetanensis*, *Isospora belli*, microsporidia, *Strongyloides stercoralis*, and from inflammatory bowel disease and irritable colon (see also Intestinal coccidia: cryptosporidiosis, isosporiasis, cyclosporiasis, Microsporidiosis, and *Strongyloides* and *capillaria*). Based on symptoms such as upper intestinal discomfort, heartburn and belching, giardiasis must also be differentiated from duodenal ulcer, hiatus hernia, gallbladder, and pancreatic disease.

Various types of malabsorption have been described including steatorrhea, disaccharidase (lactase, xylase) deficiency, Vitamin B_{12} malabsorption, hypocarotenemia, low serum folate, and protein-losing enteropathy. Lactose intolerance may persist after effective therapy, particularly in patients from ethnic groups with a predisposition for lactase deficiency. This should be considered prior to retreatment, especially if the patient continues to have diarrhea, but post-treatment negative stool specimens.

Although there is speculation that the organisms coating the mucosal lining may act to prevent fat absorption, this does not completely explain why the uptake of other substances normally absorbed at other intestinal levels is prevented (Tandon et al. 1977). Occasionally the gall bladder may also be involved, causing gall-bladder colic and jaundice. *G. lamblia* has also been identified from bronchoalveolar lavage fluid (Stevens and Vermeire 1981) and the urinary tract (Meyers et al. 1977). Reasons for such a dramatic variation in host susceptibility are not understood. Host factors such as nutritional status and both systemic and mucosal immunity may also play a role.

IMMUNOLOGY

Recent studies document antigenic variation with surface antigen changes during human infections with *Giardia*, and although the biological importance of this work is not clear, it suggests that this may provide a mechanism enabling the organism to escape the host's immune response (Nash et al. 1990). Also one would suspect that the more rapid the rate of change, the more likely that a chronic infection would be seen. Certain surface antigens may allow the organisms to survive better in the intestinal tract and might not be immunologically selected (Nash 1997).

Although patients with symptomatic giardiasis usually have no underlying abnormality of serum immunoglobulins, a high incidence of giardiasis has been shown to occur in patients with immunodeficiency syndromes, particularly in common variable hypogammaglobulinemia (Ament et al. 1973). Giardiasis was found to be the most common cause of diarrhea in these patients and was associated with mild to severe villus atrophy. Successful treatment of giardiasis led to symptomatic cure and improvement in mucosal abnormalities, with the exception of nodular lymphoid hyperplasia.

Acute (polymorphonuclear leukocyte and eosinophils) and chronic inflammatory cells have been found in the lamina propria together with increased epithelial mitoses – findings that revert to normal after therapy. The presence of these inflammatory cells has been linked to epithelial cell damage. The range of patient response is from normal to almost complete villous atrophy. Crypt mitosis is also increased based on the degree of villous damage, however, it has also been reported that mucosal changes return to normal within several days of treatment and that patients with giardiasis have reduced surface area compared with uninfected individuals.

Although no definitive pattern has been identified, it appears that lamina propria plasma cells producing immunoglobulin (Ig)M and IgE increase, whereas local production of IgA seems to be suppressed. More severe villous damage has also been reported in patients with diminished gamma globulins.

During the acute phase of giardiasis, jejunal active antigen uptake is increased, leading to delayed recruitment of mucosal and connective mast cells. These changes may influence the increased incidence of hypersensitivity reactions and allergic disease associated with *Giardia* infection (Hardin et al. 1997). Severe malabsorption has also been linked with isolated levothyroxine malabsorption, leading to severe hypothyroidism (Seppel et al. 1996) and secondary impairment of pancreatic function (Carroccio et al. 1997). In both cases, therapy with metronidazole led to complete remission of symptoms.

PATHOLOGY

Although the organisms in the crypts of the duodenal mucosa may reach very high densities, they might not cause any pathology. The organisms feed on the mucous secretions and do not penetrate the mucosa as *G. muris* does in mice where trophozoites have been recovered in

the deeper tissues (Owen et al. 1981). Although some organisms have been seen in biopsy material inside the intestinal mucosa, others have been seen attached only to the epithelium. In one in vitro study using cultured epithelial cells, the organisms showed no toxic or invasive effect (Chavez et al. 1986). Another study by Chen and colleagues has demonstrated a *G. duodenalis* cysteine-rich surface protein (CRP136) that has 57 percent homology with the gene encoding the precursor of the sarafotoxins, a group of snake toxins from the burrowing adder known to cause symptoms similar to those of humans acutely infected with *Giardia* (Chen et al. 1995). Thus, CRP136 represents the first evidence for a potential *Giardia* toxin. In symptomatic cases, there may also be irritation of the mucosal lining, increased mucus secretion, and dehydration (Erlandsen 1974; Peterson 1957). In a recent study, it appears that *G. lamblia* may cause intestinal pathophysiology by disrupting tight junctional ZO-1 and increasing epithelial permeability. Apical administration of epidermal growth factor (EGF) prevents these abnormalities and reduces epithelial colonization by the live parasites (Buret et al. 2002).

With the advent of acquired immune deficiency syndrome (AIDS), there was speculation that *G. lamblia* might be an important pathogen in this group, but clinical findings to date have not confirmed this fear (Meyer 1990; Smith et al. 1988). Although giardiasis has certainly been reported in AIDS patients, clinical experience does not suggest a more pathogenic role for *G. lamblia* in these patients than in other non-AIDS individuals.

Isoenzyme studies, primarily designed to assist in organism identification and classification, have also provided additional information regarding pathogenicity, implication in waterborne outbreaks, and human disease. In one study where isoenzyme patterns of 32 isolates of *Giardia* obtained from both humans and animals were examined, there was no obvious correlation between clinical symptoms and isoenzyme patterns. Isolates from asymptomatic individuals were found in the same zymodemes (isoenzyme groups) as isolates from symptomatic hosts. This study also confirmed previous observations regarding genetic heterogeneity and demonstrated significant differences between isolates from within a single region and other widely separated geographic locations (Proctor et al. 1989). A study from Australia provided data on two *Giardia* demes derived from children with similar chronic symptoms both of which appear to be pathogenic (Upcroft et al. 1995).

DIAGNOSIS

Generally, routine laboratory test results are normal, including hematology; eosinophilia is rare. Malabsorption of fat, glucose, lactose, xylose, carotene, folic acid, and vitamin B_{12} is occasionally present in some patients. Diagnosis of giardiasis is usually based on identification of the organisms from stool or duodenal aspirate specimens (Table 3).

Routine stool examinations are normally recommended for the recovery and identification of intestinal protozoa. In the case of *G. lamblia*, because they are attached so securely to the mucosa by means of the sucking disk, even a series of five to six stools may be examined without recovering the organisms. These parasites also tend to be passed in the stool on a cyclical basis. The EnteroTest capsule may be helpful in recovering the organisms, as may duodenal aspirates. Although cysts can often be identified on the wet stool preparation, many infections may be missed without the examination of a permanent stained smear (Collins et al. 1978; NCCLS 1997; Garcia 2001). If material from the string test (EnteroTest) or mucus from a duodenal aspirate are submitted, they should be examined as a wet preparation for motility; motility may be represented by nothing more than a slight flutter of the flagella because the organism will be caught up in the mucus. After diagnosis, the rest of the positive material can be preserved and processed for permanent staining. Experience in the clinical laboratory setting has shown

Table 3 *Laboratory diagnosis of giardiasis – key points*

Laboratory diagnosis
Even if a series of three stool specimens (ova and parasite examinations) are submitted and examined correctly, the organisms may not be recovered and identified.
Motility on wet preparations may be difficult to see because the organisms may be caught up in mucus.
Any examination for parasites in stool specimens must include the use of a permanent stained smear (even on formed stool).
Duodenal drainage either alone or in combination with the EnteroTest capsule may be very helpful in organism recovery. This technique does not take the place of the ova and parasite examination.
Immunodiagnostic procedures have been found to be more sensitive than the routine stool methods (ova and parasite examination) and are now being used routinely by some laboratories. These procedures are normally performed on order; if negative and the patient remains symptomatic, additional testing (O&P examination, special stains for the coccidia and microsporidia) can be ordered. Other considerations such as cost, training, equipment availability, batching of tests, and number of requests also play a role in test selection.

that the examination of duodenal fluid after a series of negative stool examinations rarely confirms a positive infection. This may be due to parasite location or small numbers. Because of these considerations, the examination of intestinal fluid should not replace routine stool examinations, all of which should include the use of permanent stained smears (Garcia 2001).

Procedures have also been developed using the enzyme-linked immunosorbent assay (ELISA) to detect *Giardia* antigen in feces. The ELISA is at least as sensitive as microscopic wet examinations (Addis et al. 1991; Nash et al. 1987). A fluorescent method using monoclonal antibodies has also proved extremely sensitive and specific in detecting *Giardia* in fecal specimens (Garcia et al. 1992). Many of these newer methods are being used to screen patients suspected of having giardiasis or those who may be involved in an outbreak situation (Garcia and Shimizu 1997; Aldeen et al. 1998).

A number of studies have compared the newer immunoassay products, with excellent and comparable results. Several new products are available in a cartridge format (Figure 4). Some of these use an immunochromatographic strip-based detection system for the detection of *Giardia lamblia* and *Cryptosporidium parvum*, which can be used with fresh, frozen and/or formalinized fecal specimens (Garcia and Shimizu 2000; Katanik et al. 2001; Garcia et al. 2003). A third cartridge system uses enzyme immunoassay for the detection of the *Entamoeba histolytica*/*E. dispar* group, *Giardia lamblia*, and *Cryptosporidium parvum*, which requires fresh or frozen fecal specimens (Garcia et al. 2000). Results have demonstrated that ELISA for detection of copro-antigens in a single stool sample may be almost as sensitive for the detection of giardiasis as repeated microscopy on two sequential stool samples (Mank et al. 1997).

In a study of nine different immunoassay kits for the detection of *Giardia lamblia*, the sensitivity of ELISA ranged from 94 to 99 percent; the specificity was 100 percent. All direct fluorescence assay results were in agreement with both 100 percent specificity and 100 percent sensitivity; a total of 60 specimens positive for *Giardia*, 40 specimens positive for both *Giardia* and *Cryptosporidium*, and 50 negative fecal specimens were tested. In addition to specificity and sensitivity, factors such as cost, simplicity, ease of interpretation of results, equipment, available personnel, and number of tests ordered are also important considerations prior to method selection (Garcia and Shimizu 1997).

In another study of nine commercially available ELISAs for detection of *Giardia lamblia* in fecal specimens, all except one were found to be rapid, sensitive, and specific. Sensitivities and specificities ranged from 88.6 to 100 and 99.3 to 100 percent, respectively (Aldeen et al. 1998).

Occasionally, after multiple stool examinations and examination of intestinal fluid have been negative, a small bowel biopsy may confirm the suspect diagnosis of giardiasis. It is recommended that the biopsy be taken from the area of the duodenojejunal junction; but biopsies from multiple duodenal and jejunal sites are preferred. Fluid smears and touch preparations can be air dried, fixed in methanol, and stained with Giemsa stain. The organisms appear somewhat purple and the epithelial cells appear pink. Routine histological procedures should also be performed with very careful screening of the material; trophozoites are very difficult to see and may be present in very few of the sections. Normally, the trophozoites are more likely to be seen attached to the microvillous border within the crypts.

Radiological findings from the small intestine may be normal in giardiasis, but abnormalities can occur and are usually seen in the duodenum or jejunum. Findings may include thickened mucosal folds, increased secretions, and a pattern of edema and segmentation, none of which is diagnostic for giardiasis. Approximately 20 percent of patients with giardiasis may exhibit these findings after routine barium examination. It is always recommended that the stools be collected for routine examinations prior to the patient receiving barium as organisms may be difficult to identify in the stool for several days to more than a week afterwards. Because giardiasis may not produce any symptoms at all, demonstration of the organism in symptomatic patients may not rule out alternative diagnoses such as peptic ulcer, celiac disease, strongyloidiasis, and possibly carcinoma.

Unfortunately, serodiagnostic procedures for giardiasis do not yet fulfill the criteria necessary for wide clinical use, particularly since they may indicate either past or present infection. In contrast, the detection of antigen in a stool or visual identification of the organisms using immunodiagnostic reagents indicates current infection. With the increase in numbers of *Giardia* infections and awareness of particular situations such as nursery school settings, additional detection assays have been developed as rapid and reliable immunodiagnostic procedures (Keystone et al. 1978; Craft 1982; Sealy and Schuman 1983; Addis et al. 1992; Garcia and Shimizu 1997; Aldeen et al. 1998; Garcia and Shimizu 2000; Garcia et al. 2000; Katanik et al. 2001; Garcia et al. 2003).

Recent studies using indirect fluorescent assay (IFA) to measure anti-*Giardia* humoral responses demonstrated that more than 34 percent of asymptomatic patients have a titer equal to or less than 1:500, while more than 29 percent of the symptomatic patients have a titer of 1:8000 or higher. The circulating antiparasite IgM and IgA, measured by ELISA, were significantly higher in symptomatic patients and correlated with higher cyst output (Soliman et al. 1998).

The secretory immune response to membrane antigens during *Giardia lamblia* infection in humans may be important in future studies in the diagnosis of giardiasis; these antigens were not recognized by saliva samples from healthy individuals (Rosalesborjas et al. 1998).

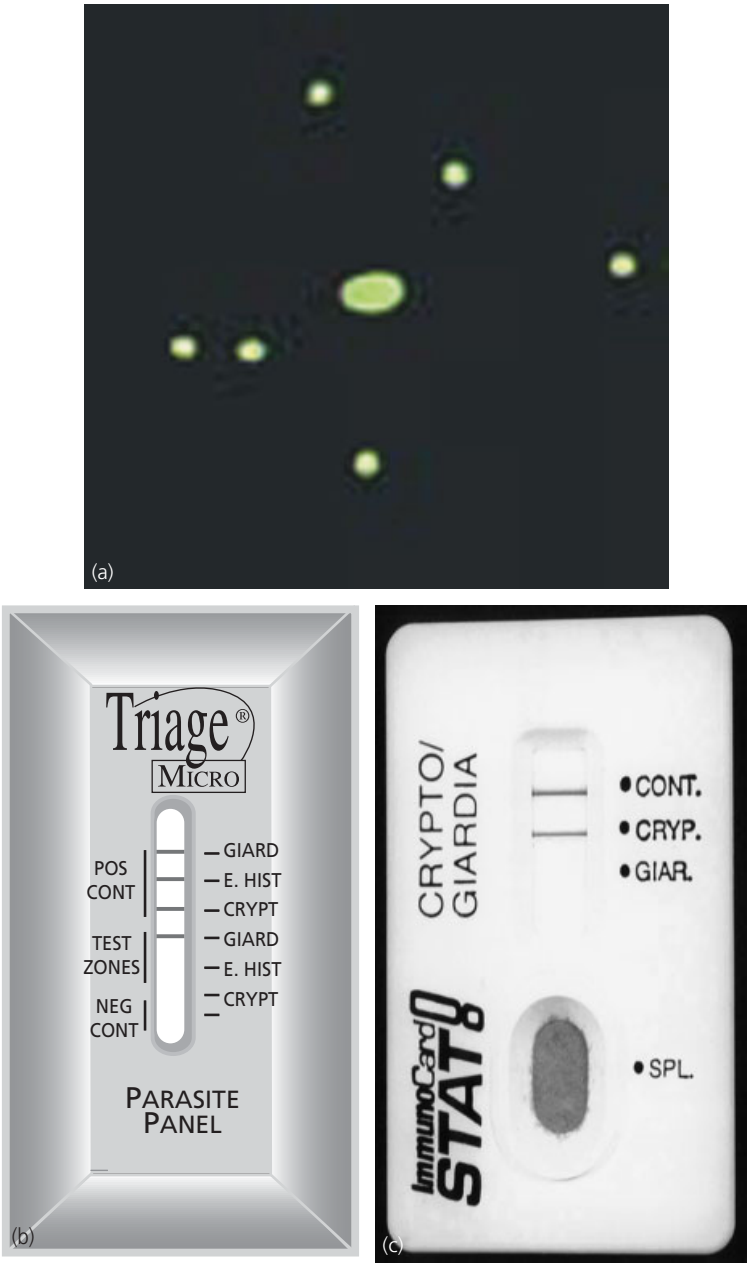

Figure 4 *Fecal immunoassays for the detection of* Giardia lamblia*:* **(a)** *Merifluor* Cryptosporidium/Giardia *combination FA reagent (Meridian Bioscience, Cinncinnati, OH) for the detection of* Giardia lamblia *cycsts (large oval structure) and* Cryptosporidium parvum *(small round objects) –can be used with preserved stools;* **(b)** *Triage® Paasite Panel (BIOSITE Diagnostics, San Diego, CA) cartridge format for the detection of* Giardia lamblia*,* Cryptosporidium parvum*, and the* Entamoeba histolytica/E. dispar *group – requires fresh stools;* **(c)** *immunochromatographic cartidge format (Meridian Bioscience, Cinncinnati, OH) for the detection of* Giardia lamblia *and* Cryptosporidium parvum.

EPIDEMIOLOGY

Giardiasis is one of the most common intestinal parasitic infections in humans and is distributed worldwide in developed and developing countries. There are, however, differences in the numbers of infections, not only between countries but also within geographic regions. Infections seem to be more common in children than adults, and other social, environmental, climatic, and economic factors also play a role in disease prevalence. Susceptibility to infection with *Giardia* is influenced by sex, age, environmental conditions, socioeconomic conditions, occupation, nutritional status, gastric acidity, and overall host immune status.

Transmission occurs through ingestion of as few as ten viable cysts. Infection can be acquired from food or water and directly person-to-person by the oro-fecal route. Often there are outbreaks due to poor sanitation

facilities or breakdowns as evidenced by travelers and campers (Kettis and Magnius 1973; Knaus 1974; Lopez et al. 1978; Moore et al. 1969). There has also been an increase in the prevalence of giardiasis in the male homosexual population, probably due to anal and oral sexual practices (Phillips et al. 1981; Schmerin et al. 1978).

Geographical distribution varies considerably worldwide with reported prevalence figures ranging from a low of 5 percent in Indonesia to 43 percent in the Seychelles; in the US, the figure is c. 7.4 percent (Islam 1990). When reviewing reported prevalence figures, it is always important to remember that data varies considerably, depending on the sensitivity and specificity of the diagnostic methods used. In areas of the world in which *Giardia* is endemic, the majority of infections in children occur in those under 10 years of age. A decrease in infections seen in children older than 10 years may reflect acquired immunity and behavioral changes that decrease potential environmental exposure to the organism. High population density and overcrowding probably contribute to higher prevalences of giardiasis. In low-income populations residing on the United States–Mexico border with no sewerage and water services, households with children under 5 years of age were 1.3 times at risk for *Giardia* infection when compared with *Cryptosporidium*. These findings highlight the differences in the transmission of these two pathogens and emphasize the need for interventions related to hygiene, water supply, and sanitation (Redlinger et al. 2002).

Although seasonal patterns have been identified for some infectious diseases, limited information is available for giardiasis. Some data suggest an association with the cooler, wetter months of the year; this is not surprising if one considers the issue of environmental conditions advantageous to cyst survival.

It has been documented that certain occupations may place an individual at risk of infection and these include sewage and irrigation workers who may become exposed to infective cysts. In situations where young children are grouped together (e.g. nursery schools), there may be an increased incidence of exposure and subsequent infection of both children and staff.

The possible association between gastric acidity and giardiasis has been debated for some time; decreased gastric acid production may predispose to infection with *Giardia*. It is thought that normal gastric acidity acts as a barrier to the establishment of an infection; patients who have had a gastrectomy are prone to infection with *Giardia*. Although achlorhydria is associated with blood group A, and some evidence suggests that this group is more susceptible to giardiasis, subsequent evidence has not confirmed this association. Since reduction in gastric acid also occurs as a result of malnutrition, these factors may be linked and, as a group, increase the susceptibility to infection with this organism. This link between malnutrition and giardiasis may also be explained by the impairment of the host's immune system.

The issue of breast milk in modifying infection with *Giardia* has also been discussed (Islam 1990). Lower incidence of giardiasis in children up to and including 6 months of age may be related to an association with breast-feeding and some protection against infection through secretory IgA. However, lower incidence may also be related to decreased exposure to *Giardia* in breast-fed infants.

Giardiasis is one of the more common causes of traveler's diarrhea and has been recorded from all parts of the world. It has also been speculated that visitors to areas endemic for *Giardia* are more likely to present with symptoms than individuals who live in the area; this difference is probably due to the development of immunity from prior, and possible continued, exposure to the organism (Soliman et al. 1998; Isaac-Renton et al. 1999).

In the USA, there have been a number of outbreaks attributed to either resort or municipal water supplies in Oregon, Colorado, Utah, Washington, New Hampshire, and New York (Craun 1990; Kirner 1978; Shaw et al. 1977; Wright et al. 1977). Most waterborne outbreaks have occurred in water systems using surface water sources (Dykes et al. 1980). High rates of infection have also been reported from hikers and campers who drank stream water: because some of these areas are remote from human habitation, infected wild animals, especially beavers, are suspected as being a possible source of infection (Dykes et al. 1980). In addition to beavers and muskrats, *Giardia* infects a number of different animals, including dogs, cats, cattle, sheep, pigs, goats, gerbils, rats, and gorillas; however, the role of some of these species in zoonotic giardiasis is uncertain (Halliday et al. 1995; Karanis et al. 1996; Graczyk et al. 2002; van Keulen et al. 2002).

Use of immunomagnetic beads to separate *Giardia* cysts from environmental surface waters, followed by DNA release and polymerase chain reaction (PCR) amplification of the target giardin gene has been used to improve the reliability of the detection of this parasite with improved sensitivity (Mahbubani et al. 1998). Another approach involves continuous separation channel centrifugation, which can simultaneously concentrate multiple pathogens as small as one micron with high and reproducible efficiency in a variety of water matrices (Borchardt and Spencer 2002). Unfortunately, cryptosporidial oocysts and *Giardia* cysts have also been found in bottled water in Brazil (Franco and Cantusio Neto 2002). It is now obvious that a large portion of the total organism loads in watercourses and in drinking water reservoirs result from rainfall and extreme runoff events. Thus, regular water samples are inadequate for accurately estimating the microbial contamination of watercourse systems. The procedures for raw-water surveillance within the context of multiple-barrier protection and risk assessment must

include sampling during extreme runoff situations (Kistemann et al. 2002). A new dye, Beljian red, has been shown to discriminate *Giardia* cysts seeded into water samples from those naturally present in the sample; this approach should be useful in determining the specific recovery of protozoan parasites from environmental samples (Ferrari et al. 2003).

The phagocytic capacity of hemocytes of the Asian freshwater clam, *Corbicula fluminea*, for *Giardia* cysts may be another useful mechanism for indicating contamination of waste waters and agricultural drainage with these parasites (Graczyk et al. 1997).

Although control efforts have emphasized water treatment issues, a recent study suggests that a number of species of rotifers ingested varying numbers of *Giardia* cysts, which were retained within the rotifers' bodies throughout the observation period. This type of ingestion may represent another means of reducing water contamination (Trout et al. 2002).

With the recently recognized efficacy of ultra-violet (UV) irradiation against *Cryptosporidium* oocysts, the inactivation of *Giardia* cysts was also investigated, as was cyst ability to repair UV-induced damage following typical drinking water and wastewater doses of 160 and 400 JM(−2). The infectivity reduction of *Giardia* cysts at these UV doses remained unchanged after exposure to repair conditions. Thus, UV disinfection at practical doses achieves appreciable (greater than 4 log) inactivation of cysts in water with no evidence of DNA repair leading to infectivity recovery (Linden et al. 2002).

During the past few years, giardiasis has received much publicity. With increased travel, there has been a definite increase in symptomatic giardiasis within the USA (Addis et al. 1992). Various surveys show infection rates of 2–15 percent in various parts of the world.

CHEMOTHERAPY

If giardiasis is diagnosed, the patient should be treated; however, the therapy is controversial, depending on geographical location in the world. In the majority of cases, giardiasis can be eliminated with the use of quinacrine, but its side-effects include: nausea, vomiting, headache, and dizziness. Vertigo, excessive sweating, fever, pruritis, corneal edema, myalgias, and insomnia have also been reported.

Metronidazole is also very effective and is approved by the World Health Organization (WHO, 1995) but is listed as the second drug of choice by the Centers for Disease Control in the United States because of potential carcinogenicity in rats and mutagenic changes in bacteria. Although these changes have never been demonstrated in humans and the issue is still debated, metronidazole is not recommended for pregnant women. The most frequent side-effects are gastrointestinal and include: nausea, vomiting, diarrhea, and crampy abdominal pain. Additional complaints may include metallic taste, headache, dizziness, drowsiness, lassitude, paresthesias, urticaria, and pruritis. Alcohol should be avoided when taking this medication. Although standard therapy usually cures the infection, some immunocompromised patients, including patients with AIDS, as well as some immunocompetent patients, have giardiasis that is refractory to therapy. Therapy with a combination of quinacrine and metronidazole has been reported to be effective (Nash et al. 2001).

Tinidazole has also been used and has proved more effective than metronidazole as a single dose (Jokipii and Jokipii 1979). Furazolidone is often used for treating children and paromomycin has been suggested for use in pregnancy (Davidson 1990).

In the absence of a parasitological diagnosis, the treatment of suspected giardiasis is a common question with no clear-cut answer. The approach depends on the alternatives and the degree of suspicion of giardiasis, both of which will vary among patients and physicians. It is not recommended that treatment be given without good parasitological evidence particularly since relief of symptoms does not allow a retrospective diagnosis of giardiasis; the most commonly used drug, metronidazole, also targets other organisms besides *Giardia*.

The third question involves treatment of asymptomatic patients. Generally, it is recommended that all cases of proven giardiasis be treated because the infection may cause subclinical malabsorption, symptoms are often periodic and may appear later, and a carrier is a potential source of infection for others. Certainly, in areas of the world where infection rates are extremely high, as well as the prospect of reinfection, the benefit per cost ratio also has to be examined.

INTEGRATED CONTROL

Because of the potential for wild animal, and possibly other domestic animal, reservoir hosts, other measures as well as personal hygiene and improved sanitary measures have to be considered (Brightman and Slonka 1979; Hewlett et al. 1982). Iodine has been recommended as an effective disinfectant for drinking water, but it must be used according to the appropriate directions (Jarroll et al. 1980; Jarroll et al. 1981; Zemlyn et al. 1981). Filtration systems have also been recommended, although they have certain drawbacks, such as clogging. Water-treatment systems tend to be unavailable in developing countries, many of which do not have piped water available to the general population. Boiling the water is effective, but carries with it the cost of fuel, another consideration in many parts of the world. Improved personal hygiene, routine hand-washing, better preparation and storage of food and water, control of insects that may come in contact with infected stools and then contaminate food or water, and treatment of symptomatic and asymptomatic individuals

would all lead to a decrease in the overall numbers of infections with this parasite.

Although the potential for a vaccine has been discussed, prospects are poor for the development of actual vaccine reagents in the near future. Control measures will continue to be centered on environmental and personal hygiene issues.

INTRODUCTION

Of the three to five trichomonad species found in humans, only *Trichomonas vaginalis* regularly displays the capacity for producing disease. Human trichomoniasis persists and is essentially cosmopolitan in its occurrence despite the availability of effective chemotherapeutic agents and little evidence of the development of significant drug resistance. A sexually transmitted disease, trichomoniasis caused by *T. vaginalis* ranges from a mild or inapparent infection to one causing a chronic and substantial level of inflammation in the reproductive tract of women and significant urethritis in men (Krieger et al. 1993a). Rare cases of perinatal infection of females born to infected mothers (Sobel 1992; Smith et al. 2002; Szarka et al. 2002) and respiratory trichomonad infections (Walzer et al. 1978) have been reported, the latter possibly attributable to trichomonads other than *T. vaginalis*.

CLASSIFICATION

T. vaginalis is a parasitic protozoan and is classified as follows:

Class Trichomonadea, Kirby, 1947

Order Trichomonadida, Kirby, 1947 emend. Honigberg, 1974. There are typically 4–6 flagella, which may be recurved, free or attached to an undulating membrane (when present). There are usually no true cysts.

Family Trichomonadidae, Wenyon, 1926. Characterized by possession of: a cytostome; 3–5 free flagella (one flagellum on the margin of an undulating membrane); and an axostyle protruding through the posterior of the cell.

Genus Trichomonas, Donné, 1837. Trophozoites that typically possess: 4 free flagella (one along the outer margin of the undulating membrane); a costa at the base of the undulating membrane; and an axostyle. No cysts are present.

STRUCTURE AND LIFE CYCLE

The shape of *T. vaginalis* is typically pyriform in culture, although ameboid shapes are evident in parasites adhering to mammalian cells (Nielsen and Nielsen 1975). Light- and electron-microscopic studies (Honigberg and King 1964; Nielsen 1975), summarized by Honigberg and Burgess (1994), indicate that *T. vaginalis* is c. 9.7 × 7 μm and that nondividing organisms have four anterior flagella. In addition to the flagella (four anterior and one recurrent) the undulating membrane and the costa also originate in the kinetosomal complex at the anterior of the parasite. Internal organelles include a prominent nucleus and a rigid structure, the axostyle, that runs through the cell from the anterior to posterior end (Figure 1).

Figure 1 Trichomonas vaginalis *from culture, stained with Giemsa's stain, showing axostyle (left) and undulating membrane (arrow). Four distinct anterior flagella are visible (right). Bar = 10 μm. (Courtesy of M. Tighe, VMBL)*

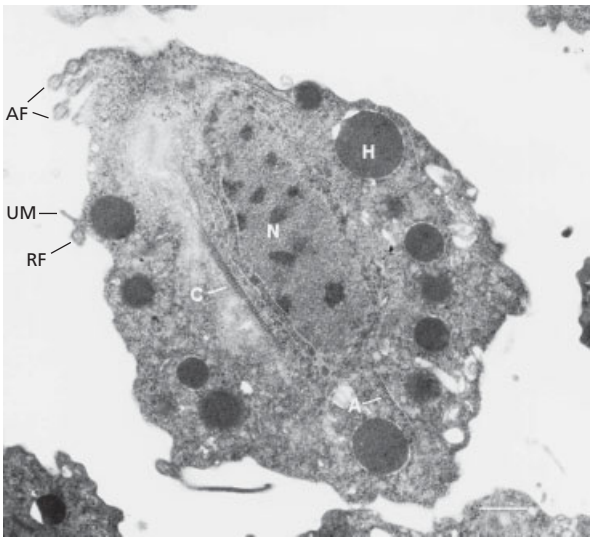

Figure 2 *Transmission electron micrograph of* Trichomonas vaginalis *from culture showing: axostyle (A), costa (C), hydrogenosome (H), nucleus (N), anterior flagella (AF), recurrent flagellum (R), undulating membrane (UM). Bar = 1 μm. (Courtesy of A. Blixt, VMBL)*

A respiratory organelle, the hydrogenosome (Lindmark and Müller 1973), is present and appears by light microscopy as a paraxostylar and paracostal chromatic granule. The hydrogenosome is seen as an osmiophilic, dense granule by electron microscopy (Nielsen 1975, 1976) (Figure 2).

The life-cycle of *T. vaginalis* is simple in that the trophozoite is transmitted through coitus and no cyst form is known. The trophozoite divides by binary fission giving rise to a population in the urogenital tract of humans.

BIOCHEMISTRY, MOLECULAR BIOLOGY, AND GENETICS

Anaerobic metabolism produces most of the parasite's energy. Earlier work on the biochemistry of *T. vaginalis* (reviewed in Shorb 1964; von Brand 1973; Honigberg 1978) indicated that several sugars (e.g. maltose, glucose) are fermented by the parasite through a glycolytic pathway. Subsequent studies revealed that transport of glucose across the cell membrane occurred by facilitated diffusion (ter Kuile and Muller 1992). The metabolism of *T. vaginalis* differs from that of eukaryotic cells with mitochondria in three major areas:

1 the importance of inorganic pyrophosphates in carbohydrate catabolism
2 the importance of sulfur proteins in metabolism
3 the disposal of electrons by the formation of molecular hydrogen (Searle and Müller 1991; Müller 1992).

Trichomonads lack both cytochrome-mediated electron transport and the associated electron transport-linked phosphorylation, as well as the familiar mitochondrion that houses this system in other eukaryotic cells. Instead, the site of fermentative carbohydrate metabolism is the hydrogenosome (Lindmark and Müller 1973; Müller 1992), an organelle thought to have arisen by endosymbiosis with an anaerobic bacterium, or conversion of mitochondria (Lahti et al. 1992). Hydrogenosomes isolated from *T. vaginalis* have an NADH/ferredoxin oxidoreductase activity and these organelles ferment pyruvate to acetate, malate, molecular hydrogen and cxarbon dioxide. Pyruvate is also converted to acetyl-CoA via ferridoxin–oxidoreductase activity (Johnson et al. 1990; Land et al. 2001). This fermentation is dependent on adenosine diphosphate (ADP), inorganic phosphate, magnesium and succinate, and carbon dioxide-dependent carboxylation of pyruvate to malate by malate dehydrogenase. Detergent disruption (Triton X100) stops pyruvate-dependent formation of molecular hydrogen (this effect is overcome by adding exogenous ferredoxin), indicating that the structural integrity of the hydrogenosome is crucial to its effective functioning (Steinbuchel and Müller 1986).

The mechanism of development of anaerobic resistance to metronidazole also is controlled by hydrogenosomes in that metronidazole competes for hydrogen ions as an electron acceptor. In metronidazole-resistant *T. vaginalis* the expression levels of the hydrogenosomal enzymes (pyruvate:ferredoxin oxidoreductase, ferridoxin,

malic enzyme, and hydrogenase) are reduced dramatically which is likely to eliminate the ability of the parasite to activate metronidazole (Land et al. 2001).

Hydrolytic enzymes

Proteinases of *T. vaginalis* have been known since the 1970s and detailed investigations of these enzymes have been made during the last 10 years. Cysteine proteinases seem to be particularly prevalent, as dithiothreital stimulates the activity of several proteinases from *T. vaginalis*. These range from 20 to 110 kDa (Lockwood et al. 1987), the lower molecular weight proteinases being released from the cell (Lockwood et al. 1984, 1987, 1988; North et al. 1990). The release of proteinases from *T. vaginalis* is of interest in the context of its ability to elicit varying degrees of inflammation and the possible role of these enzymes in pathogenesis. There are reports of cell-detaching factors released by the parasite into the growth medium (Garber et al. 1989; Lushbaugh et al. 1989) some of which are reported to have trypsin-like activity. These factors are active on human and hamster cells, causing them to detach and round up. Release of cell-detaching factors and proteinases from *T. vaginalis* clearly implies that these parasite products could degrade proteins such as laminin, vitronectin and other components of the extracellular matrix, thus effecting the release of host cells from tissue.

The substrate specificity and structure of some of the proteinases of *T. vaginalis* are now being determined. Parasite proteinases were not inhibited by pepstatin, phenyl methyl sulphonyl fluoride or EDTA, but they were inhibited by iodoacetic acid, antipain, leupeptin and N-a-p-tosyl-L-lysine chloromethyl ketone. Lower molecular sizes of proteinases were released from the parasite; proteinases of 25, 27, and 34 kDa specifically hydrolyzed synthetic substrates with arginine–arginine residues whereas other proteinases had activity over a wide substrate range (North et al. 1990). Recent cloning studies of cysteine proteinase genes of *T. vaginalis* indicate that at least four distinct genes are present and that they have considerable homology (up to 45 percent identity) with cysteine proteinase genes of *Dictyostelium discoideum*. Three of the proteinase genes were present as single copies, whereas the other was present as a multiple copy gene. The amino acid sequence data indicated that these proteinases were of the L/cathepsin H/papain type (Mallinson et al. 1994).

Nucleic acids

Nucleic acid synthesis in trichomonads differs markedly from that in mammalian cells, as trichomonads do not synthesize either purines or pyrimidines de novo. *T. vaginalis* does not incorporate purine-ring precursors into nucleic acids but rather directly salvages purine nucleosides through adenosine and guanosine kinases. Neither inosine nor hypoxanthine are incorporated and no interconversion between adenylate and guanylate occurs (Heyworth et al. 1982). Trichomonads are also unable to synthesize pyrimidines from aspartate, orotate and bicarbonate, the typical de novo pathway. Neither thymidylate synthetase nor dihydrofolate reductase activity has been found. Conversion of cytidine by cytidine phosphotransferase and nucleotide kinases to cytidine monophosphate (CMP), cytidine diphosphate (CDP) and cytidine triphosphate (CTP) allows *T. vaginalis* to salvage exogenous cytidine, uridine, uracil and, to some extent, thymidine into its nucleotide pool (Wang and Cheng 1984). Cytidine is converted to uridine by cytidine deaminase, whereas uracil is converted to uridine by uridine phosphorylase before conversion into nucleotides. Nucleosides (but not nucleotides) are transported across the cell membrane of *T. vaginalis*. The nucleosides adenosine, guanosine and uridine are transported across the cell membrane by a two-carrier, facilitated transport mechanism at a rate apparently sufficient to sustain growth (Harris et al. 1988). Intracellularly, nucleosides are rapidly converted to nucleotides so that transport is not affected by any appreciable build up of nucleosides. Neither bases nor D-ribose affect uptake of nucleosides, suggesting that the carriers operating in *T. vaginalis* are similar to those in other parasitic protozoa such as *Plasmodium berghei* (Hansen et al. 1980) and *Leishmania donovani* (Aronow et al. 1987).

CLINICAL ASPECTS

T. vaginalis is site-specific, usually surviving in only the urogenital tract of humans although rare cases of pneumonia in newborns have been reported (Smith et al. 2002; Szarka et al. 2002). Approximately 10 percent of vulvovaginitis is due to infection with *T. vaginalis* (Sobel 1992). In men, clinical features of the infection may include urethral discharge and inflammation of the tissues lining the reproductive/urinary tract (Krieger et al. 1993a), but it is more usual for men to display no symptoms.

A female patient infected with *T. vaginalis* may have no obvious clinical signs or may suffer vaginitis of varying severity. Asymptomatic patients can also carry the infection and remain at risk of developing symptomatic disease at a later date (Krieger et al. 1988). Clinical features that may develop in 50–90 percent of infected women include: purulent vaginal discharge, pruritus, and dyspareunia. Leukorrhea and dysuria are occasionally seen. Vaginal discharge is observed in 50–75 percent of diagnosed women and is considered malodorous in only c. 10 percent of these patients. Although the discharge has often been described as yellow–green and frothy, only c. 8 percent of patients produce a discharge characterized as frothy and c. 59 percent produce a discharge characterized as

purulent. Diffuse vulvar erythema and copious vaginal discharge are often present. Punctate hemorrhages of the cervix may result in a strawberry-like appearance, apparent by inspection in only 1–2 percent of patients but apparent in 45 percent of patients examined by colposcopy (Wølner-Hanssen et al. 1989). Pruritus, particularly vulvar itching, is a frequent symptom (25–50 percent of patients) and may be severe (Sobel 1992).

IMMUNOLOGY

Some of the earliest investigations into immunity centered on reports that sera obtained from a variety of mammals can lyse *T. vaginalis* and agglutinate the parasite. Although earlier investigators considered lysis to be dependent on antibody action, *T. vaginalis* is now known to activate complement by the alternative pathway (Gillin and Sher 1981). An extensive study of normal human, bovine, sheep, horse, swine, and dog sera against *T. vaginalis* (Reisenhofer 1963, summarized by Honigberg 1970) showed that these sera had low (equal to or less than 1:64) but consistently detected agglutinating activities. Current understanding of immunity to *T. vaginalis* is unsatisfactory and it is not clear whether induced immunity is protective and if so, how. Although there is evidence that protection may be achieved by immunization of laboratory animals, strong protective immunity does not seem to follow natural infection in humans. Immunosuppressed persons, such as those with acquired immune deficiency syndrome (AIDS), do not develop fulminating *T. vaginalis* infections despite the high prevalence of the parasite in the general population. A recent study of patients infected with *T. vaginalis* and human immunodeficiency virus (HIV) indicated no evidence of increased levels or longevity of parasite infection in these patients compared to patients with *T. vaginalis* but without HIV (Cu-Uvin et al. 2002). These observations may indicate that innate immunity involving chemotaxis and subsequent influx of neutrophils are much more important than acquired immunity in controlling infections with *T. vaginalis* since neutrophils are often the most numerous leukocytes present in sites of infection.

Innate immunity

Innate immune responses to *T. vaginalis* are well documented and may be important in controlling infection as well as in inflammation during infection. Both macrophages and polymorphonuclear neutrophils (PMN) have been shown to be capable of killing *T. vaginalis* in vitro (Rein et al. 1980) and PMNs have been reported to be attracted to a factor(s) secreted by live *T. vaginalis* (Mason and Forman 1980). Leukocytic vaginal discharge was previously considered to be an important clinical finding expected in women infected with *T. vaginalis*, but more recent studies indicate no significant difference between the numbers of infected and uninfected women with vaginal discharge (Fouts and Kraus 1980). Even so, recruitment of macrophages and PMNs to the site of infection (by the sensitized T lymphocytes and the lymphokines they produce, or by parasite-derived factors that are directly chemotactic for PMNs) could be important elements in protective immunity and the pathological changes present in persons with trichomoniasis.

Acquired immunity

Early experimental studies on acquired immune responses to *T. vaginalis* examined various immunizations of laboratory animals and evaluated antibody from patients with *T. vaginalis* infection. Guinea pigs given intraperitoneal inoculations of vaginal material containing trichomonads produced antibody responses, as did rabbits given formalin-killed parasites (Riedmuller 1932; Tokura 1935). In mice, intramuscular inoculation induced protection against challenge infection that lasted at least 15 weeks (Kelly and Schnitzer 1952; Schnitzer and Kelly 1953). Intramuscular injection of *T. vaginalis* protected up to 100 percent of mice against an intraperitoneal challenge, but much less protection was afforded against a subcutaneous challenge (Kelly et al. 1954). The protective effect of sera from infected humans was shown in experiments in which human sera were transferred to mice inoculated intraperitoneally with *T. vaginalis*. Similar mouse inoculation experiments with human sera or rabbit hyperimmune sera indicated that these antibodies were both protective. Levels of protective antibodies in the sera of patients quickly diminish following elimination of infection (Teras and Nigesen 1969; reviewed in Honigberg 1970). The conclusion from these and subsequent observations (Sobel 1992) is that although an immune response to *T. vaginalis* occurs in infected patients and produces circulating antibody against the parasite, the response is short-lived and does not provide protection against re-infection.

Antibody responses during infection with *T. vaginalis* have been evaluated in numerous surveys by several immunoassays (summarized in Honigberg and Burgess 1994). Although some infected patients do not have detectable anti-*T. vaginalis* antibodies, most display secreted and circulating (serum) antibodies. Secretory antibody levels in the reproductive tract seem to increase in women infected with *T. vaginalis* and parasite-specific antibodies occur in the urogenital tract of persons harboring *T. vaginalis*. Immunoglobulin IgA antibody, specific for *T. vaginalis*, was present in vaginal secretions of 76 percent of 29 infected women and 42 percent of 19 apparently uninfected women with higher levels in the infected patients (Ackers et al. 1975). Subsequent reports have verified the presence of

parasite-specific antibody in vaginal secretions. Street et al. (1982) reported that 73.2 percent of infected women had anti-*T. vaginalis* IgG or IgA antibodies, compared to 41 percent of uninfected women. Additional studies on a women with proven *T. vaginalis* trichomoniasis have confirmed these findings (Romia and Othman 1991; Alderete et al. 1991a).

Early evidence that a cellular immune response is elicited in patients infected with *T. vaginalis* is based on the observation that such patients develop positive delayed-type hypersensitivity (DTH) reactions to whole parasite antigen preparations (Adler and Sadowsky 1947; Aburel et al. 1963). Later it was shown that blood lymphocytes from individuals with active infections proliferated in vitro when stimulated with whole cell antigen preparations; lymphocytes from uninfected persons gave minimal responses (Yano et al., 1983a, 1983b; Mason and Patterson 1985). Similar results have been obtained in early studies of DTH reactions (summarized in Honigberg and Burgess 1994) and lymphocyte proliferation responses in mice (Mason and Gwanzura 1988). These results, together with the findings in patients, indicate that systemic sensitization of T lymphocytes can occur during infection.

Antigens

Early immunological studies of *T. vaginalis* indicated that there were antigenic differences between geographically distinct strains of this parasite. In a series of studies in the 1960s, four serotypes (TLR, TN, TRT, and TR) were described by the use of cross-agglutination and complement fixation methods. These serotypes had common and unique antigens and were present in a large geographical area of central and eastern Europe (reviewed by Honigberg 1970). In another study, agglutination, complement fixation and fluorescent antibody methods were used to demonstrate three serotypes of *T. vaginalis* in one geographical area of the former USSR (Andreeva and Mihov 1976). This report was among the first to describe molecular differences between strains of *T. vaginalis* and to attempt to correlate these with serological type; on the basis of the electrophoretic patterns of ten strains of *T. vaginalis*, five different antigenic groups were detectable. Since this initial work, numerous antigens of *T. vaginalis* have been described, some being shared between strains and others being strain-specific.

Subsequently, antigens of *T. vaginalis* have been partially characterized including limited information about function. In one study, 20 immunogenic polypeptides, ranging from 20 to 200 kDa, were detected with rabbit antisera (Alderete 1983) many of which were determined to be on the parasite surface (Alderete et al. 1985). Additional studies using monoclonal antibodies prepared against one clone of *T. vaginalis*, showed that these monoclonal antibodies reacted with surface epitopes on four of nine distinct parasite clones (Torian et al. 1984; Connely et al. 1985). Western blot analysis of reactions indicated the presence of both conserved and heterogeneous epitopes and antigens (Torian et al. 1988).

Some isolates of *T. vaginalis* possess a 270 kDa surface antigen (P270) that is strongly expressed, whereas other isolates express little P270 on their surface (Alderete et al. 1986a, b). Expression of higher amounts of P270 correlates with lower *T. vaginalis* cytotoxicity toward HeLa cells, suggesting that the degree of expression of P270 may be a useful virulence marker. A 6-amino acid epitope of P270 (DREGRD) binds experimental antibodies specific for P270, as well as a high percentage of the antibody in serum from infected patients, suggesting that P270 could be an immunodominant antigen (Alderete and Neale 1989; Dailey and Alderete 1991). Additional *T. vaginalis* antigens have been detected, including a 230 kDa surface antigen that binds to vaginal antibodies present in infected patients (Alderete et al. 1991a) and proteinases that elicit serum and secreted antibodies (Alderete et al. 1991b; Bozner et al. 1992). Four antigenic surface molecules have also been implicated in the adhesion of *T. vaginalis* to vaginal epithelial cells, their expression being upregulated during attachment to host cells (Arroyo et al. 1993). Antibodies to these molecules protect target cells from parasite-mediated cytotoxicity (Arroyo et al. 1992) suggesting that anti-adhesion immune responses could be important in protecting against the pathogenic effects of *T. vaginalis*.

PATHOLOGY

Although *T. vaginalis* was first described by Donné (1836), its role as a cause of vaginitis was not recognized for another 80 years (Höhne 1916). The early report of Hogue (1943) on the pathogenic effects of *T. vaginalis* on cells in cultures suggested that the parasite could directly damage host cells. The clinical features, including pathogenicity, of human urogenital trichomonads have been reviewed (Jírovec and Petru 1968; Brown 1972; Catterall 1972; Honigberg 1990; Honigberg and Burgess 1994). Trichomoniasis is a frequently encountered, sexually transmitted disease (Lossick and Kent 1991) and a common cause of vaginitis and exocervicitis (Heine and McGregor 1993; Sobel 1992). Children born to women with trichomoniasis may suffer from low birth weight (discussed by Heine and McGregor 1993; Gibbs et al. 1992; Cotch et al. 1991), probably as a result of tissue damage from the cytopathic effect of this parasite on mammalian cells (Alderete and Perlman 1983; Krieger et al., 1985a).

Histological findings

Histological findings in women with trichomonad cervicitis have been described (Koss and Wolinska 1959); up

to one-third of biopsies of female patients infected with *T. vaginalis* show no histological changes. Patients displaying changes had increased vascularity of the squamous epithelium and the presence of the trichomonads was often accompanied by distension of blood vessels within papillae. The 'strawberry cervix' (Lang and Ludmir 1961; Fouts and Kraus 1980) appearance of the exocervix is due to the local extravasation of blood resulting in petechiae (rather than to ulceration) and is not usually due to inflammation. There is more pronounced dilation of epithelial vessels in patients with trichomonad cervicitis compared with those with nontrichomonad-induced cervicitis. Edema of the squamous epithelium is accompanied by separation of epithelial cells from each other, inflammation of the squamous epithelium, and desquamation. Perinuclear haloes may develop that can be confused with the koilocytotic atypia caused by human papilloma virus infection (Quinn and Holmes 1984); these are often confined to the basal layers of the epithelium. A proportion of epithelial cells display a variety of other abnormalities including enlarged nuclei, hyperchromasia and binucleation. Pyknotic nuclei are evident in the damaged epithelium indicating necrosis and a purulent exudate often coats the epithelial surface; such findings are rare in nontrichomonad cervicitis. Biopsy material from 11 women infected with *T. vaginalis* was examined by Nielsen and Nielsen (1975) in an electron microscope study. Generally, there was evidence of chronic nonspecific inflammation with subepithelial infiltration by neutrophils and lymphocytes. Three of the patients had cervical erosion; the lumens of the glands were packed with neutrophils. In cases of more severe inflammation, neutrophils were present in deeper layers of the epithelium, the neutrophils near the surface being arranged in lacunae. *T. vaginalis* was occasionally found on the surface of the stratified squamous epithelium in clusters situated in areas of shallow depression in the epithelial surface. The trichomonads were often seen on the vaginal surface in a dense mantle, but were not attached to the epithelium in observations in seven patients. Ameboid trichomonads attached only to necrotic epithelial cells with the undulating membrane on the surface away from the substrate. In the areas of contact between parasites and epithelial cells, there was interdigitation of cytoplasmic projections from the parasite and host cell, which is evidence of intimate contact between the parasite and host during human infection. In women with florid vaginitis, the secretion typically contains numerous motile trichomonads, thus rendering diagnosis reasonably easy. In women with latent trichomoniasis, in which the parasite has retreated into the cervical region and in which bizarre and atypically hyperplastic cells may be present in smears, the trichomonads are more difficult to find. In the diffuse or patchy inflammatory secretion, the trichomonads may not be motile. *T. vaginalis* is often difficult to recognize in routinely fixed and stained smears (such as those stained with hematoxylin and eosin). Antibody-based immunohistochemical procedures have been developed that compare favorably with wet mount methods (Kreiger et al. 1988).

Mechanism of pathogenicity

Studies of the cytopathic effects of *T. vaginalis* on a variety of cell lines in vitro provide support for a cytopathic mechanism in which both parasite–host cell contact and soluble factors play a role. It was previously known that efficient killing of several target cell lines by *T. vaginalis* required close approximation or contact between parasite and target (Krieger et al. 1985a; Alderete and Garza 1985, 1988). Evidence that parasite adhesion to target cells is important for induction of damage of targets has come from experiments in which various treatments, (Arroyo and Alderete 1989), low temperature (4°C) (Alderete and Garza 1985), cytochalasin D (Krieger et al. 1985a), trypsin (Alderete and Garza 1985), or cysteine proteinase inhibitors lowered adhesion of parasites to targets. These studies suggested that proteinaceous surface structures synthesized by the parasite played a role in adhesion. Four antigenic surface molecules have specifically been implicated in the adhesion of *T. vaginalis* to host cells (Enbring and Alderete 1992) and parasites in contact with HeLa cells or vaginal epithelial cells increase their expression of these adhesion molecules (Arroyo et al. 1993). Although these reports indicate that intimate association of *T. vaginalis* to targets leads to efficient killing in these experimental systems, they do not prove the absence of one (or more) soluble mediators responsible for host cell damage. There are several reports of soluble factors produced by *T. vaginalis* that are active against nucleated host cells (Garber et al. 1989; Lushbaugh et al. 1989; Pindak et al. 1986). Although most of the cell-detachment factors remain uncharacterized there is a recent report of a soluble lytic factor with phospholipase activity (Lubick and Burgess 2004). When homogeneous preparations of such molecules become available, the precise structure and function of such factors will be established and a better understanding of the mechanisms of pathogenesis of trichomoniasis at the molecular level will be possible.

DIAGNOSIS

Microscopy and culture procedures are the most widely used methods for the detection of *T. vaginalis* in men and women. The most commonly employed procedures are:

- direct microscopic examination of fresh (stained or unstained) material in wet mounts, accomplished with the aid of bright-field, dark-field, or phase-contrast microscopy

- microscopic examination of fixed and stained preparations, usually smears, stained with Giemsa's stain
- cultivation employing a variety of media.

A combination of the wet mount and culture procedures is both efficient and cost-effective in detection of *T. vaginalis*-positive cases among both women and men. Reports of an improved culture device, InPouch™ (BioMed Diagnostics Inc.), indicate that it compares favorably with standard culture procedures in a clinical setting (Draper et al. 1993; Levi et al. 1997; Barenfanger et al., 2002).

Immunological methods have not been used widely for diagnosis of *T. vaginalis* infection although the relative specificity and sensitivity of individual techniques has been improved recently. In a comparison of several methods, direct detection of *T. vaginalis* using fluorescein-labeled monoclonal antibody compared favorably with wet mounts, staining of fixed material and culture (Krieger et al. 1988). Immunohistochemical methods detected the related trichomonad, *Tritrichomonas foetus*, in sections of formalin-fixed tissue from the reproductive tract of infected cattle more easily than standard microscopic methods (Burgess and Knoblock 1988; Rhyan et al. 1995).

Antibody and antigen detection

Several types of enzyme-linked immunosorbent assay (ELISA) (Engvall and Perlman 1971) have been developed for *T. vaginalis*, either to measure patient antibodies or to detect antigens of *T. vaginalis* in clinical samples. In one example, whole-cell antigen preparations of *T. vaginalis* (Street et al. 1982) together with aqueous extracts (Alderete 1984) were used as antigens to detect antibodies in serum and vaginal secretions of patients. Affinity-purified, rabbit antibodies to *T. vaginalis* have been used as both capture and detection antibodies in a sandwich ELISA to detect antigens of *T. vaginalis* (Watt et al. 1986). This assay had a sensitivity of 77 percent, a specificity of 100 percent, and was more sensitive than microscopic examination of wet mounts, but less sensitive than culture methods for detection of infection. Detection of *T. vaginalis* antigens in fluids on vaginal swabs by ELISA had a sensitivity of 93.2 percent and a specificity of 97.5 percent in a study of 44 culture-positive patients in a study group of 482 (Yule et al. 1987). Employing a monoclonal anti-*T. vaginalis* antibody as a capture and detection antibody, a sensitivity of 89 percent and a specificity of 97 percent have been achieved (Lisi et al. 1988).

Molecular methods

Nucleic acid hybridization methods for detection of *T. vaginalis* (Rubino et al. 1991) have sensitivity and specificity as good as culture methods. Riley et al. (1992) developed a polymerase chain reaction (PCR) method, using primers that produced a 102. bp product, termed A6p. They used the method to test 24 isolates of *T. vaginalis*, all of which reacted positively and similar results have been obtained with another PCR method using a different target (Kengne et al. 1994). In both cases, PCR procedures produced no false positive reactions with template DNA from sources such as human cells, other parasitic protozoa and viruses. A PCR assay using primers based on beta-tubulin sequences of *T. vaginalis* detected 22 of 23 culture-positive samples (Madico et al. 1998). Also, PCR methods were able to detect a higher prevalence in males than was detected by culture methods (Schwebke and Lawing 2002) and positive PCR results have recently been suggested as diagnostically useful where trichomoniasis may be undertreated (Wendel et al. 2002).

EPIDEMIOLOGY AND CONTROL

Trichomoniasis persists throughout the world, despite the availability of effective chemotherapeutic agents and seemingly adequate awareness of the disease on the part of physicians, public health workers and the general population (Schwebke 2002). In recent years, there has been a focus on *T. vaginalis*, due partly to heightened awareness of sexually transmitted diseases generally, as well as the fact that people with *T. vaginalis* infections seem to be at higher risk of HIV infection than are uninfected persons.

Infections with *T. vaginalis* are quite common; the prevalence of *T. vaginalis* in nonselected female populations is probably 5–20 percent. Most estimates of prevalence are based on data from selected patient populations (e.g. those attending sexually transmitted disease clinics); such estimates are unlikely to be representative of the population at large. Even so, the data indicate that there has been a slow decline in the prevalence of *T. vaginalis* infections over the past 20 years. In 1972, more than 180 million women and men were estimated to be infected with *T. vaginalis* worldwide (Brown 1972), including c. 2.5 million women in the USA and 1 million women in the UK (Catterall 1972). *T. vaginalis* infection prevalence in American women is estimated at 3 million cases annually (Rein 1990) and some investigators consider trichomoniasis to be the most common sexually transmitted protozoan disease (Levine 1991) and perhaps even the most common sexually transmitted disease (Hammill 1989). Although estimates in nonselected male populations are not as certain as for women, the prevalence in men is probably c. 50–60 percent of that in women (Rein and Müller 1989). One study noted a prevalence of 11 percent in men attending an STD clinic (Krieger et al. 1993b) which is comparable to the 17 percent recently detected in a similar study (Schwebke and Lawing 2002).

CHEMOTHERAPY

Treatment of vaginal trichomoniasis relies on the 5-nitroimidazole compounds: metronidazole, tinidazole, and ornidazole. Metronidazole is the only one of these currently recommended by the WHO (Schwebke 1995). Tinidazole with metronidazole have comparable efficacies when used in a single-dose regimen (Gabriel et al. 1982). Metronidazole acts by interfering with DNA synthesis, apparently as the result of the production of a transient cytotoxic intermediate form (Lossick 1990). Daily treatment for 7 days or treatment by a single 2 g dose gave equivalently high cure rates (more than 90 percent) (Lossick 1982). The daily treatment regimen consists of oral administration of 250 mg of metronidazole three times daily for 7 days, producing a cure rate of c. 95 percent (Lossick 1990; Sobel 1992). Although the multiple-dose regimen is efficacious for the patient even without treatment of the sexual partner, it suffers from a degree of noncompliance. The single-dose regimen is particularly effective if used with simultaneous treatment of sexual partners, but it does not protect against the relatively frequent event of prompt reinfection by untreated sexual partners. Because of the multifocal nature of infection with *T. vaginalis*, systemic (rather than local) treatment is preferred. In fact, endogenous reinfection by parasites harbored in the urethra and periurethral glands is known to occur when local treatment is attempted (Rein and Muller 1989).

VACCINATION

There is no vaccine currently available for use against *T. vaginalis*. The search for vaccines against protozoa is complicated by their ability to evade and modulate host immune responses. *T. vaginalis* may be able to evade the immune response as it exists largely outside the host in the lumen of the reproductive tract. Effector mechanisms such as secretory antibody (sIgA) may prove to be crucial in protection against the cytotoxic effects of this parasite on host cells. Many basic questions concerning the immune response to *T. vaginalis* remain unanswered and such lack of knowledge impedes vaccine development. For example, we do not know the mechanisms by which natural infections are eliminated, nor which target antigens elicit protective immunity. We do not even know if an effective protective immunity develops during natural infection. The absence of an appropriate laboratory animal model for trichomoniasis has delayed progress in answering these questions. The natural history of infection by *T. vaginalis* in humans suggests that adaptive immune responses during infection do not play a significant role in controlling infections. Indeed, the most prevalent leukocyte response in the reproductive tract during infection is by neutrophils and chemotaxis of neutrophils by components of *T. vaginalis* has been reported (Mason and Forman 1980). These findings, together with the pattern of frequent reinfection, suggest that effective immunological memory may not be established in most infected persons. Other explanations for the absence of protective immunity after infection are the presence of a considerable number of distinct antigenic types of *T. vaginalis* (Krieger et al. 1985b), or the occurrence of some form of antigenic drift over time, as has been observed with certain surface antigens (Alderete et al. 1986b). A combination of these phenomena could produce a re-infection pattern similar to that seen with the rhinoviruses that cause the common cold. If such drifts occur, new antigenic profiles in the parasite population would occur so rapidly that the host could not effectively respond to the ever-changing epitopes being displayed.

INTEGRATED CONTROL

Control of trichomoniasis due to *T. vaginalis* should include:

- thorough examination to determine infection status of the patient
- appropriate treatment of the patient and sexual partner(s)
- continued surveillance by public health agencies to provide updated prevalence estimates.

Current knowledge of the immune response to *T. vaginalis* is insufficient to predict whether the development of a vaccine represents a realistic goal. A rational vaccine development strategy should include research toward understanding the roles of certain surface antigens and secreted antigenic molecules (e.g. proteinases) and identification of new target antigens.

Dientamoeba fragilis and other intestinal flagellates

JAROSLAV KULDA AND EVA NOHÝNKOVÁ

Introduction	1	*Chilomastix mesnili*	5
Dientamoeba fragilis	1	*Retortamonas intestinalis*	7
Enteromonas hominis	5	References	8

INTRODUCTION

The digestive tract of humans can serve as habitat for several species of flagellates belonging to protozoan orders Trichomonadida, Diplomonadida, and Retortamonadida. Besides *Giardia* and the trichomonads discussed in Giardiasis and *Trichomonas* infections, these are *Dientamoeba fragilis*, *Enteromonas hominis*, *Chilomastix mesnili*, and *Retortamonas intestinalis*. All are confined to the large intestine, the habitat with low digestive activity and an abundance of the intestinal flora. Although diverse in morphology and subcellular organization, these flagellates are united by their ability to live and multiply under anaerobic or microaerophilic conditions. All seem to depend on associated bacterial biocenosis for both nutrition and adjustment of proper physicochemical conditions. However, their metabolism remains unknown since they are rarely obtained in a condition suitable for biochemical experiments. Also, genomic studies are scarce and limited to sequence analyses of rRNA genes for phylogenetic investigations. The life cycles of most of these organisms are simple and direct and do not involve sexual processes.

Typically, these organisms alternate the proliferative trophozoite, multiplying by binary fission in the host intestine, and the resting resistant cyst that is discharged with feces and serves to transmit the infection. *Dientamoeba* does not produce cysts and is an exception from this generalization. Infection with the cyst-producing flagellates is acquired through contaminated food and water or by direct fecal–oral transmission. Just one of the species discussed (*D. fragilis*) is an enteropathogen of clinical importance; the remaining species are harmless commensals. Some pathogenic potential was ascribed to *Chilomastix* but has not been proved. An increase in the flagellate population is often secondary to a pathological condition of another etiology, indicating merely that the intestinal biocenosis is out of balance. Still, even the nonpathogenic intestinal flagellates deserve consideration both from the diagnostic standpoint and as indicators of a poor standard of personal hygiene and sanitation.

DIENTAMOEBA FRAGILIS

Classification

Dientamoeba fragilis Jepps and Dobell, 1918 is an unusual flagellate with no flagella and was originally classified as an ameba. However, further morphological studies by Dobell (1940) revealed its relationship to *Histomonas meleagridis*, a turkey pathogen related to the trichomonads. Dobell noticed the presence of centrodesmus (centrodesmose), a fiber connecting the nuclei of the binucleate forms of *Dientamoeba* and later identified as the extranuclear spindle characteristic for the mitosis of Trichomonadida. Trichomonad affinities were unequivocally proven by the electron microscopic studies of Camp et al. (1974) and further confirmed by molecular phylogenies based on a complete sequence of the small subunit rRNA gene (Silberman et al. 1996). Biological, clinical, and diagnostic aspects of *Dientamoeba* have been recently reviewed (Johnson et al. 2004).

Structure and life cycle

Dientamoeba occurs in a trophozoite stage only and does not encyst. Low resistance of trophozoites to unfavorable environmental conditions, failure to infect humans and primates with cultured trophozoites (Dobell 1940), and the close relationship with *Histomonas* led to the assumption that *Dientamoeba*, like *Histomonas*, can develop in a helminth vector. Burrows and Swerdlow (1956) proposed the pinworm *Enterobius vermicularis* as a probable vector and pinworms eggs as a vehicle for *Dientamoeba* transmission. Uninucleate ameboid cells have been observed in pinworm eggs (Burrows and Swerdlow 1956; Ockert 1990) but convincing direct evidence of their identity with *Dientamoeba* is lacking.

Trophozoites of *Dientamoeba* usually measure 7–12 μm in diameter although they can vary within a wider range (3.5–22 μm). They are uninucleate or binucleate with predominance of binucleate forms (60–80 percent) resulting from protracted telophase of the parasite mitosis. Nuclei are rounded with a central group of chromatin granules and delicate nuclear membrane without adjacent peripheral chromatin (Figure 1). The extranuclear mitotic spindle can be seen in properly stained binucleate forms as a fibril extending between the nuclei (Figures 1 and 2c).
Dientamoeba produces blunt pseudopodia and feeds by phagocytosis of bacteria or other particles such as rice starch in culture (Figure 2a, b).

Electron microscopy shows a profoundly reduced but recognizable pattern of the trichomonad cell (Camp et al. 1974), with typical association of striated parabasal fibrils and Golgi dyctiosomes into the parabasal apparatus, presence of the extranuclear mitotic spindle, and double-membrane-bound organelles corresponding to hydrogenosomes. *Dientamoeba* lacks kinetosomes, microtubular structures such as axostyle and pelta, and

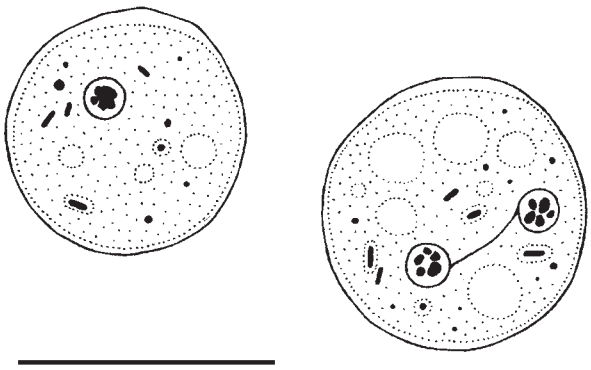

Figure 1 Dientamoeba fragilis*: uninucleate and binucleate trophozoites. Note the typical arrangements of chromatin granules within the nuclei and a fiber representing the extranuclear mitotic spindle (paradesmose) connecting the nuclei in the binucleate form. Based on iron-hematoxylin stained specimens. Bar = 10 μm.*

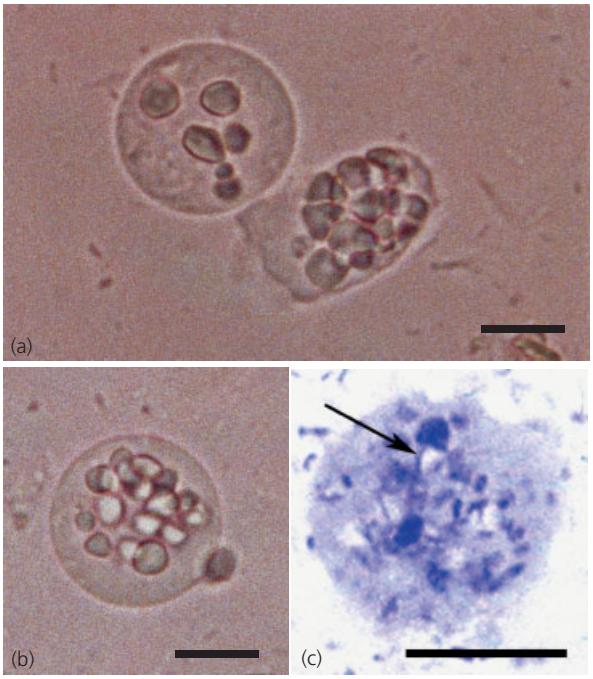

Figure 2 Dientamoeba fragilis*:* **(a, b)** *fresh mount from culture, trophozoites with ingested rice starch grains;* **(c)** *binucleate trophozoite with extranuclear spindle (arrow). Giemsa–Romanowski stain. Bar = 10 μm.*

any type of centriole. Microtubule organizing centers of the mitotic spindle are attached at the inner side of the base of parabasal fibrils that assume polar position in the mitotic cells. The cytoplasm contains glycogen granules and numerous food vacuoles (secondary lysosomes) with ingested particles in different phases of digestion. Mitochondria are absent.

Biochemistry and molecular biology

No experimental data are available on the biochemistry of *Dientamoeba*. The presence of hydrogenosomes and susceptibility to metronidazole suggest that the pyruvate-metabolizing pathway linked to ferredoxin-mediated electron transport known to operate in the hydrogenosome of trichomonads, is also functional in *Dientamoeba*.

The gene for small subunit ribosomal RNA (SSU rRNA) was cloned and sequenced for phylogenetic studies (Silberman et al. 1996) and fragments of this gene obtained by polymerase chain reaction amplification with trichomonad-specific primers, were used for riboprinting of *Dientamoeba* isolates (Johnson and Clark 2000). The genotyping of *Dientamoeba* based on direct amplification from human stool samples was reported by (Peek et al. 2004).

Clinical aspects

Despite controversies about the primary role of *D. fragilis* in the etiology of gastrointestinal disorders, suffi-

cient evidence is available to demonstrate that the organism is pathogenic (reviewed by Yang and Scholten 1977; Ockert 1990; Windsor and Johnson 1999). Symptomatic infections with *Dientamoeba* occur in both children and adults. The most frequent symptoms are abdominal pain, intermittent diarrhea, flatulence, and fatigue, sometimes accompanied by nausea, vomiting, and anorexia. The disease usually has a chronic, recurrent character and often is associated with a peripheral eosinophilia that is more common in children than in adults (Spencer et al. 1979, 1982). Acute diarrhea or cases presenting as eosinophilic or ulcerative colitis have also been observed (Cuffari et al. 1998; Shein and Gelb 1983). Disappearance of symptoms after elimination of *Dientamoeba* by chemotherapy from patients where *D. fragilis* was the only pathogen detected, have been reported repeatedly (Kean and Malloch 1966; Spencer et al. 1979; Ockert 1990). *Dientamoeba* can cause diarrhea in those with acquired immune deficiency syndrome (AIDS). Although the prevalence of *Dientamoeba* infection is higher in groups that are positive for human immunodeficieny virus (HIV) than in groups not infected with HIV (Mendez et al. 1994), there is no conclusive evidence that the pathogenic effect is more severe in HIV-positive patients than it is in HIV-negative individuals (Lainson and da Silva 1999).

Immunology

No systematic study on the immune response to the infection with *D. fragilis* has been published so far. Peripheral eosinophilia has been reported repeatedly, but its significance is not known. Chan et al. (1996) employed indirect immunofluoresence assay in a seroprevalence study of *Dientamoeba* infection in children and confirmed by immunoblotting with representative sera that the dominant antibody response is directed against a 39 kDa protein of *D. fragilis*.

Pathology

Histopathologic studies on appendices removed from young patients infected with *Dientamoeba* showed changes in the intestinal wall that varied from suppurative appendicitis to lymphoid hyperplasia and marked fibrosis in connective tissue of the submucosa (Burrows et al. 1954). The authors concluded that *D. fragilis* is noninvasive and assumed that irritation caused by the protracted presence of the parasite can induce low-grade inflammatory changes in the appendix that ultimately lead to fibrosis. In contrast, Shein and Gelb (1983) observed by sigmoidoscopy an invasive ulcerative process with numerous punctiform ulcers in the intestine of a woman infected with *Dientamoeba*. Flat ulcers and both acute and chronic inflammatory changes were demonstrated on biopsy but *Dientamoeba* was absent in aspirates from the areas of ulceration. According to Ockert (1990) inflammatory changes of the mucosa of rectum and sigmoid region of colon were relatively frequent in patients infected with *D. fragilis*, usually displaying a picture of low-grade chronic proctitis.

Diagnosis

Infection by *D. fragilis* should be considered in differential diagnosis in patients with abdominal pain, diarrhea, flatulence, vomiting, and unexplained eosinophilia. Unfortunately, awareness of the infection is low and methods used in many laboratories are unsuitable for the detection of this parasite. Examination of permanently stained smears prepared from fresh stools is mandatory for successful laboratory diagnosis of *Dientamoeba*; cultivation significantly increases parasite detection. It is essential that the fecal specimens are preserved and fixed or inoculated in suitable media soon after defecation, as survival time of *Dientamoeba* trophozoites is short. The collected specimens must not be refrigerated. Routine coprological concentration techniques are useless because *D. fragilis* does not form cysts, and trophozoites are destroyed during the procedure. Chan et al. (1993) reported employment of indirect immunofluoresence to facilitate detection of *D. fragilis* in stools.

Schaudin/polyvinyl alcohol fixative/preservative followed by iron hematoxylin or trichrome stain or a non-mercury-based alternative EcoFix followed by EcoStain (Garcia and Shimizu 1998), as recommended for differentiation of intestinal amebae, are suitable methods for microscopic diagnosis of *Dientamoeba*. The main diagnostic characters are nuclear morphology and presence of binucleate cells. The extranuclear spindle can be recognized occasionally and, if visible, can support the diagnosis unequivocally.

Diagnostic cultivation can be performed in the simple biphasic medium of Dobell and Laidlaw or in the more complex Robinson's medium (Clark and Diamond 2002). The Dobell–Laidlaw biphasic medium is essentially a slant of coagulated horse serum overlaid with Ringer's solution containing native egg white and supplemented with rice starch powder. By using this medium, Ockert (1990) reported an increase in detection efficiency in a large (over 1000) random sample of people in Halle, Germany from c. 2 percent diagnosed from stained fecal smears alone to c. 39 percent diagnosed from a combination of microscopy and cultivation. *Dientamoeba* usually multiplies in a primary culture and often survives for several subcultures, but successful establishment of a long-term culture is rare. Robinson's medium may facilitate establishment of cultures as it is designed to exert partial control over the concomitant bacterial flora. It is preconditioned by inoculation of a standard strain of *Escherichia coli* and unwanted associates are suppressed by erythromycin added to the medium at each subculture.

Epidemiology

DISTRIBUTION

Infections with *D. fragilis* occur worldwide (Windsor and Johnson 1999) with higher prevalence in children than in adults, and in women than in men. Although some published data are difficult to compare due to different sensitivities of the detection methods used, it is apparent that the infection is relatively frequent. In studies based on large samples of stools examined for parasites over 2–5 years, the incidence of the infection varied from 4 to 30 percent (Yang and Scholten 1977; Ockert 1990; Windsor et al. 1998). Prevalence studies in Germany and the USA (Ockert 1990; Grendon et al. 1995) showed the highest frequency of infection in children aged 6–9 years (47 percent), with variations between 10 and 82 percent observed in individual communities of children in Germany (Ockert 1990). Higher infection rates are usually linked to crowded conditions and poor standards of personal hygiene. Reports on the highest prevalence in adults (up to 50 percent) concern inmates of certain mental institutions and other closed or semicommunal groups (Wenrich 1944; Windsor and Johnson 1999). Interestingly, infections by the cyst-forming intestinal protozoa are most prevalent in a different age group (3–5-year-olds) and co-infections with *Dientamoeba* occur less frequently than those among other intestinal flagellates and amebae. Reported high prevalence and differences in age and sex distribution of subjects infected with *Dientamoeba* and other intestinal protozoa suggest that factors involved in *D. fragilis* transmission are unique to this species.

TRANSMISSION

The transmission of *Dientamoeba* is not completely resolved. The relatively high prevalence of the parasite is in sharp contrast to the absence of a resistant cyst stage and the fragility of the trophozoite, which does not survive in water (Wenrich 1944), and its viability in feces decreases rapidly. Moreover, the trophozoites were found to die in a solution simulating gastric juice (Yang and Scholten 1977), and attempts to infect a human volunteer and primates with trophozoites from culture given per os were unsuccessful (Dobell 1940). Thus, transmission by fecally contaminated food or water as well as direct fecal–oral transmission is unlikely.

In analogy with the closely related poultry pathogen *Histomonas meleagridis*, dissemination of *D. fragilis* infection by eggs of a helminth vector was proposed (Dobell 1940) and indirect evidence has been accumulated that the pinworm *Enterobius vermicularis* might be the hypothetical vector (Burrows and Swerdlow 1956; Yang and Scholten 1977; Ockert 1990). Association of infections with *D. fragilis* and pinworm has been observed at histological examination of human appendices (Burrows and Swerdlow 1956; Ockert 1990; Červa et al. 1991) as well as by routine examination for parasites, if proper detection methods were used (Yang and Scholten 1977; Ockert 1990). Statistical treatment confirmed that the frequency of these co-infections is significantly higher than would be expected at random, independent distribution of the parasite. Also, the increased prevalence of *Dientamoeba* in young people and women reflects a similar distribution of pinworm infections. Moreover, Ockert (1990) performed successful experimental self-infections with *D. fragilis* by ingesting washed pinworm eggs obtained from children infected with both *Enterobius* and *Dientamoeba*. There is also a report on *Dientamoeba* infection that followed accidental acquisition of enterobiosis by a person collecting perianal samples for pinworm diagnosis (Burrows and Swerdlow 1956).

Burrows and Swerdlow (1956) observed ameboid cells resembling mononuclear *Dientamoeba* trophozoites in eggs of pinworm females from subjects infected with *D. fragilis,* but not in worms from patients free from *Dientamoeba* infection. Ockert (1990) confirmed the presence of ameboid cells in the lumen of pinworm eggs and inside larvae encapsulated in the eggs. He further showed that these objects and *Dientamoeba* trophozoites from culture have the same value for isoelectric point after methylene blue staining. However, unequivocal identification of *Dientamoeba* in pinworms is lacking and attempts to isolate this parasite from pinworm eggs or larvae in culture were unsuccessful (Burrows and Swerdlow 1956; Yang and Scholten 1977; Ockert 1990).

Chemotherapy

Symptomatic *Dientamoeba* infections have been successfully treated with iodoquinol, metronidazole, secnidazole, chloramphenicol, tetracycline, and paromomycin (see Johnson et al. 2004 for references). Many authors consider iodoquinol (di-iodohydroxyquinoline) as the drug of choice for adults. Metronidazole and paromomycin have been used with success in children (Preiss et al. 1991; Cuffari et al. 1998).

It is difficult to recommend control measures against *Dientamoeba* infection without full knowledge of the factors involved in its transmission. However, strong indications for pinworm involvement suggest that good personal hygiene, such as that recommended for the prevention of enterobiosis, may be appropriate. Concurrent treatment for both *Enterobius* and *Dientamoeba* should also be considered when a patient infected with *Dientamoeba* belongs to a community where pinworm infections have been diagnosed.

Conclusions

Dientamoeba is a neglected pathogen that deserves higher awareness from diagnostic laboratories, clinicians

and researchers. The infection rate of *Dientamoeba* all over the world appears to be higher than originally thought, but successful diagnosis depends heavily on proper collection and processing of fecal specimens. The enteropathogenic potential of *Dientamoeba* for both children and adults has been documented and efficient chemotherapy is available. Therefore, it would be desirable to consider *D. fragilis* infection more consistently in differential diagnosis of gastrointestinal disorders and laboratories should adapt their diagnostic protocols to ensure dependable diagnosis of the parasite. The unsolved problems of the parasite life cycle and transmission should be revisited, as new techniques are now available to face this challenge.

ENTEROMONAS HOMINIS

Classification

Enteromonas is the type genus of the suborder Enteromonadina, which comprises uninucleate members of the protozoan order Diplomonadida. An ultrastructural homology of enteromonads with higher Diplomonadida such as *Hexamita* is evident (Brugerolle 1975). By topology of cell structures and organelles, *Enteromonas* resembles one half of a typical diplomonad. An evolutionary route from simple enteromonad-like forms to organisms with the double karyomastigont characteristic of higher Diplomonadida has been proposed and supported by a phylogenetic analysis based on ultrastructural characters (Siddal et al. 1992).

Structure and life cycle

Enteromonas hominis da Fonseca, 1915 is a small, cyst forming flagellate, inhabiting the cecum and other parts of the large intestine of humans and primates (Dobell 1935). The broadly oval trophozoites measure approximately 4–8 μm by 3–5 μm and possess three anterior flagella and one recurrent flagellum attached along two-thirds of the body length and continuing thereafter with a free portion. The adherent part of the recurrent flagellum is accompanied by a darkly staining fibril. The oval nucleus is located in the anterior part of the body, with its longer axis perpendicular to the longitudinal axis of the cell (Figures 3a and 4). The cysts are oval or subspherical with one to four nuclei; four nucleate cysts are considered mature.

Electron microscopy (Brugerolle 1975) revealed the presence of a narrow, shallow cytostomal groove on the ventral surface of the cell that follows the attached portion of recurrent flagellum. The lateral margins of the groove are elevated and each reinforced by a microtubular band descending from the kinetosomal area. The recurrent flagellum is lodged inside the cytosomal depression. *Enteromonas* feeds on bacteria that are endocytosed in the bottom of the cytostomal groove all along its length; cytopharyngeal tube is not developed. The cytoplasm contains numerous food vacuoles and rough endoplasmic reticulum, but mitochondria, Golgi apparatus, and microbodies are absent.

Diagnosis

Cultivation on biphasic media of the Dobell-Laidlaw type is the best method for diagnosis of *Enteromonas hominis*. Identification of this organism in stools may be difficult even on permanently stained smears processed by routine techniques. The protargol silver stain can help with accurate determination (Figure 4).

Epidemiology

DISTRIBUTION

Infections with *Enteromonas hominis* occur worldwide, but their incidence is usually low. An increased prevalence in a population (up to 10 percent) indicates poor hygienic standards.

POTENTIAL PATHOGENICITY AND TREATMENT

Enteromonas is generally considered to be a harmless commensal and treatment is not recommended. However, occasional cases of symptomatic infections in the absence of detectable pathogens have been reported (Spriegel et al. 1989; Goldberg 1990). As symptoms resolved when parasites were eliminated by treatment with metronidazole, the authors advocate use of this drug in similar cases.

CHILOMASTIX MESNILI

Classification

The genus *Chilomastix* belongs to the protozoan order Retortamonadida. Besides the human parasite, the genus includes other species that inhabit the intestines of numerous vertebrate and some invertebrate hosts. A free-living species has also been described.

Structure and life cycle

Chilomastix mesnili (Wenyon, 1910) Alexeieff, 1912 is a cyst-forming flagellate living in the cecum and colon of humans. The trophozoites are pyriform with a rounded or flattened anterior end and a tapered posterior projection (Figures 3b and 5). They measure 14 × 6 μm on average, ranging from 6–20 μm in length and 4–7 μm in width. *Chilomastix* possesses three anterior flagella and one recurrent flagellum confined to the cytostomal cavity. The cytostome forms a large cleft in the dorsal cell surface, extending from the anterior end for half the body length. Two cytostomal fibrils support

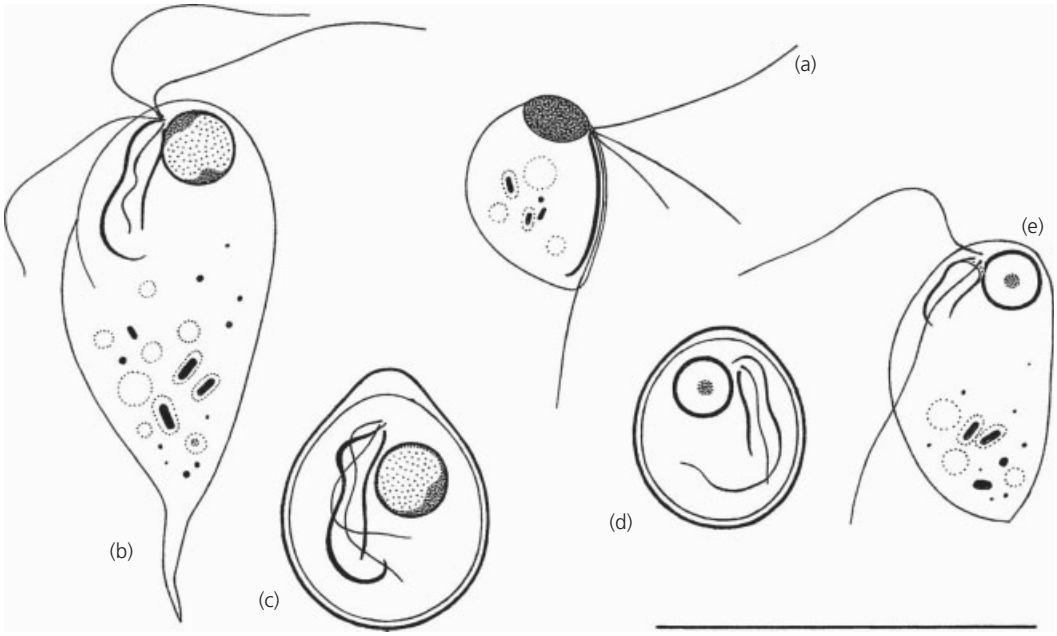

Figure 3 *Flagellates from the large intestine of humans, semidiagrammatic representation based on protargol stained specimens:* **(a)** Enteromonas hominis *trophozoite;* **(b, c)** Chilomastix mesnili*:* **(b)** *trophozoite,* **(c)** *cyst;* **(d, e)** Retortamonas intestinalis*:* **(d)** *cyst,* **(e)** *trophozoite. Bar = 10 μm.*

the edges of the cytostome. The fibril associated with the right cytostomal lip is prominent, characteristically curved, and turned round the posterior end of the cleft toward the tube of cytopharynx. The fibril of the left lip is straight and less conspicuous. The spherical nucleus is located dorsally at the anterior margin of the cell. The cysts are lemon-shaped with a broadly rounded posterior end and narrowed anteriorly. They measure 6–10 by 4–6 μm and contain a single nucleus, internalized flagella and both cytostomal fibrils (Figure 5).

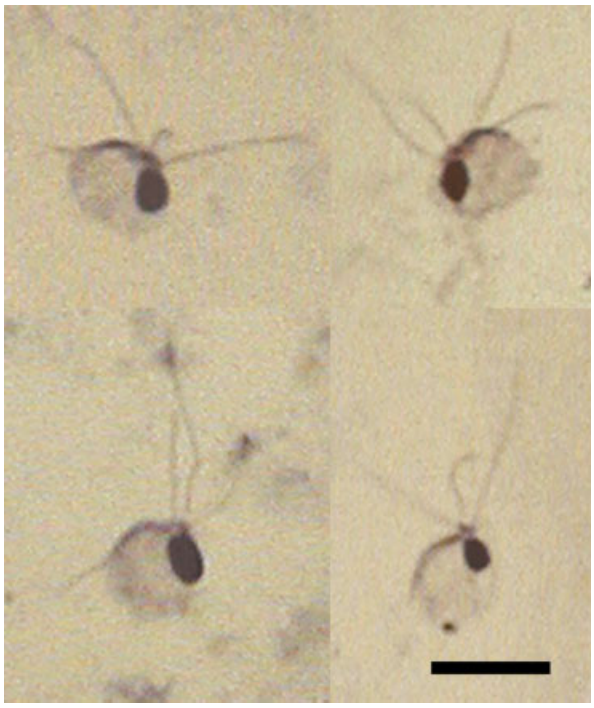

Figure 4 Enteromonas hominis *trophozoites. Protargol silver strain. Bar = 5 μm.*

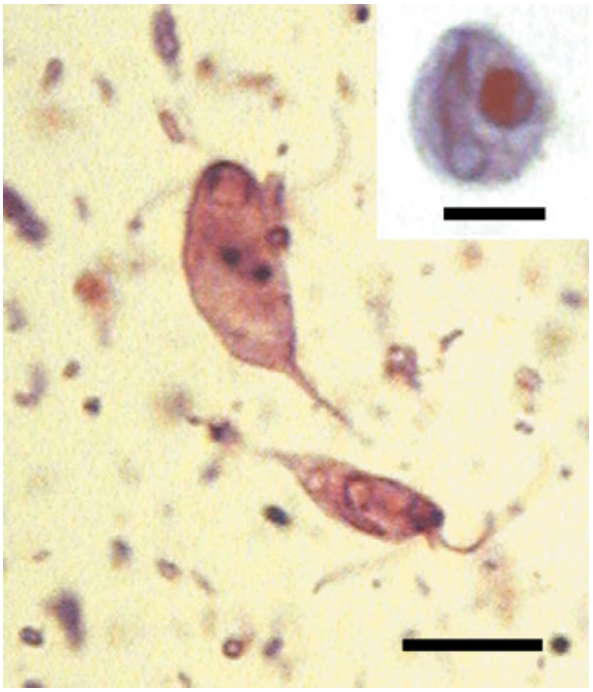

Figure 5 Chilomastix mesnili *trophozoites. Protargol silver stain. Bar = 10 μm. Insert:* Chilomastix mesnili *cyst. Iron-hematoxylin stain. Bar = 5 μm.*

Electron microscopy revealed details of components and the assembly of cytoskeletal structures associated with kinetosomes, cytostome, and cytopharynx, and showed that the cell is completely surrounded by a corset of subpellicular microtubules (Brugerolle 1973). The trophozoite cytoplasm contains numerous food vacuoles and rough endoplasmic reticulum but lacks mitochondria, Golgi apparatus, and any type of microbody-like organelles. Endocytosis of bacterial food takes place in a microtubule-free area of the cytopharynx.

Potential pathogenicity

It is generally accepted that *C. mesnili* is nonpathogenic and its association with diarrhea does not reflect a causal relationship. Therefore, no specific therapy is recommended. Occasional case reports ascribing pathogenic potential to this organism are not very convincing, excepting a single well-documented study. Červa and Větrovská (1958) investigated the etiology of periodic outbreaks of watery diarrhea in a community of institutionalized children aged 1–3 years and concluded that *Chilomastix* was responsible for the disease. Affected children passed four to ten stools in a day; diarrhea was painless but caused a moderate dehydration, decreased weight gain or loss of weight. Infectious origin of the outbreaks was evident and linked to unsatisfactory hygienic conditions in common bathrooms. No bacterial pathogens were found despite repeated examination and symptoms were insensitive to antibacterial chemotherapy. When *Chilomastix* was detected as a potential agent of the infection, the children were treated with carbasone. The treatment resulted in the elimination of parasites and disappearance of symptoms, and marked improvement in weight gain followed. These observations suggest that the possibility of *Chilomastix* occasionally acting as moderate pathogen for small children should not be entirely ignored.

Diagnosis

Trophozoites can be found in soft or liquid stools, cysts predominate in the formed stools. Both trophozoites and cysts can be easily recognized on permanently stained smears by their characteristic morphology – in particular, by the presence of cytostome with the prominent, characteristically curved cytostomal fibril. Cultivation on biphasic media such as Dobell–Laidlaw medium can increase diagnostic recovery.

Epidemiology

DISTRIBUTION AND TRANSMISSION

Distribution of *Chilomastix mesnilli* in humans is cosmopolitan with incidence ranging from 0.2 to 1 percent in standard surveys. No marked differences can be seen in the results of surveys performed in Germany, USA, Mexico, Chile, Indonesia, and Australia. Increased prevalence of the infection has been reported in specific groups with a history of diarrhea; for example, in US troops deployed in Egypt (11 percent, Oyofo et al. 1997), closed communities of institutionalized children (40 percent, Červa and Větrovská 1958) or selected groups of diarrheic patients (12.3 percent, Felsenfeld and Young 1946). No significant differences have been observed in the infestation rate of *Chilomastix* in HIV-positive and HIV-negative groups (Mendez et al. 1994). The species of *Chilomastix* occurring in monkeys and pigs is probably identical with *C. mesnili* as indicated by morphology and by successful experimental transmissions of the human flagellate to these animals. However, natural infections of animals are infrequent; about 1 percent of pigs have been found infected in surveys performed in Europe and the USA.

Interhuman transmission of the *C. mesnili* infection doubtless is of primary importance. Infection of humans by cysts of animal origin cannot be ruled out, but has not been documented. Good sanitation and personal hygiene can prevent the infection.

RETORTAMONAS INTESTINALIS

Classification

Retortamonas is the type genus of the protozoan order Retortamonadida. The genus includes numerous species inhabiting the intestines of vertebrate and invertebrate hosts. A phylogenetic analysis based on sequences of the gene for SSU rRNA (Silberman et al. 2002) showed close relationship of retortamonads to Diplomonadida.

Structure and life cycle

Retortamonas intestinalis (Wenyon and O'Connor, 1917) Wenrich, 1932 is a rare inhabitant of the human cecum. It is a small cyst-forming flagellate with trophozoites of an elongated pyriform shape, measuring 4–8 by 3–4 μm and equipped with a cytostome (Figure 3e). The cytostomal cleft of oval shape is supported by two lateral fibrils of unequal length and covered anteriorly by a membranous roof. In routinely stained specimens, the margin of the roof together with both lateral fibrils may appear as a single fibril rounding the anterior edge of the cytostome and extending posteriorly along each side. A tube-like cytopharynx extends from the cytostomal groove into the cell interior and ingested bacteria are endocytosed at its end. *Retortamonas* possesses two flagella; the anterior flagellum is free, the recurrent flagellum passes through the cytostomal groove and after emerging from it continues as a relatively long free portion. The spherical nucleus is located at the anterior margin of the cell. Mitochondria, Golgi apparatus, and

microbody-like organelles are absent. Arrangements of the *Retortamonas* cytoskeleton and other ultrastructural features of this parasite were described by Brugerolle (1977). The cysts are ovoid with a narrowed anterior end; they measure 4.5–7 by 3–4.5 μm and contain a single nucleus, internalized flagella, and cytostomal fibrils (Figure 3d).

Potential pathogenicity

Although the parasite has also been detected in diarrheic stools, there is no evidence of its pathogenicity. Therefore, no treatment is indicated. Metronidazole has been successfully used to clear the parasite from an unusual localization in the pancreatic juice of a patient with choledocholithiasis (Kawamura et al. 2001).

Diagnosis

Identification of trophozoites and cysts of *Retortamonas* on permanently stained smears stained by standard methods may be difficult but is possible. Small size, presence of the cytostome, and the spherical, apically localized nucleus can help in recognition of the organism even if the flagella are not clearly visible. Protargol silver stain can be used for exact determination. The best method for diagnosis is cultivation on biphasic media for intestinal protozoa and subsequent examination of cultured flagellates by phase contrast microscopy or in fixed and stained preparations.

Epidemiology

DISTRIBUTION AND TRANSMISSION

Infections of humans with *R. intestinalis* are infrequent, with a low prevalence even in groups living under conditions of poor personal hygiene and unsatisfactory sanitation (up to 2 percent). Autochthonous infections have been reported from all continents except Europe. Infection is alimentary, transmitted by cysts disseminated by fecal contamination. Retortamonads of similar morphology live in a variety of mammals, but zoonotic transmission is unlikely. The morphologically identical monkey parasite is considered to be conspecific with *R. intestinalis*, but attempts to infect monkeys by the human flagellate failed (Dobell 1935).

Balantidium coli

VIQAR ZAMAN AND F.E.G. COX

Historical introduction	1	Epidemiology	6
Classification	1	Chemotherapy	7
Structure and life cycle	1	Integrated control	7
Biochemistry	4	References	7
Clinical aspects	5		

HISTORICAL INTRODUCTION

Balantidium coli is the only ciliate known to infect humans and can cause dysentery. Asymptomatic infections are not uncommon, but actual disease is rare and fewer than 1 000 cases of balantidial dysentery have ever been reported. In contrast, infection in pigs is extremely common and it is generally believed that pigs act as the main reservoir for human infection. The subject has been reviewed by Zaman (1993).

Historically, the genus *Balantidium* was first recognized by Claparède and Lachmann (1858–61), who found these ciliates in the rectum of frogs. Since then *Balantidium* species have been found in a variety of animals (Corliss 1979). In 1856 Petr Henrik Malmsten, a Swedish physician, found a ciliate in the dysenteric feces of two Swedish patients which, after wide consultation with Swedish, Norwegian, and Irish colleagues, he called *Paramoecium coli* (Malmsten 1857). This ciliate was indisputably *Balantidium coli* and in 1861 Rudolf Leuckart discovered a similar organism in the large intestine of a pig (Leuckart 1861). Shortly afterwards, Stein pointed out that the human parasite described by Malmsten and the pig ciliate described by Leuckart were morphologically identical and named them both *Balantidium coli* (Stein 1863). Several sightings of other ciliates from humans were made in the 19th and early 20th centuries (see Dobell and O'Connor 1921; Wenyon 1926) but these are no longer regarded as valid. Some early writers have suggested that Leeuwenhoek actually saw this ciliate and was even suffering from balantidial dysentery, suggestions that Dobell (1920, 1932) robustly dismisses. For many years there was some controversy concerning whether or not the species in humans, and pigs are the same and whether *B. coli* from pigs can infect humans, but there now seems to be no doubt that both of these statements are true (see Dobell and O'Connor 1921).

CLASSIFICATION

The genus *Balantidium* belongs to the phylum Ciliophora, class Litostomatea, order Vestibuliferida, and family Balantidiidae (Lee et al. 1985). McDonald (1922) proposed that the pig and human species should be separated as *B. suis* and *B. coli*. This separation has not been accepted, and the parasites in the two hosts continue to be regarded as a single species by most authors.

STRUCTURE AND LIFE CYCLE

Structure

B. coli has a trophozoite and a cyst stage. The trophozoite is actively motile and is the invasive stage; the cyst is the resistant form and the infective stage. The length of the trophozoite varies from 30 to 300 μm and the width from 30 to 100 μm (Sargeaunt 1971). The body shape is also variable, but is generally ovoid and slightly flattened on one side (Figures 1 and 2). At the

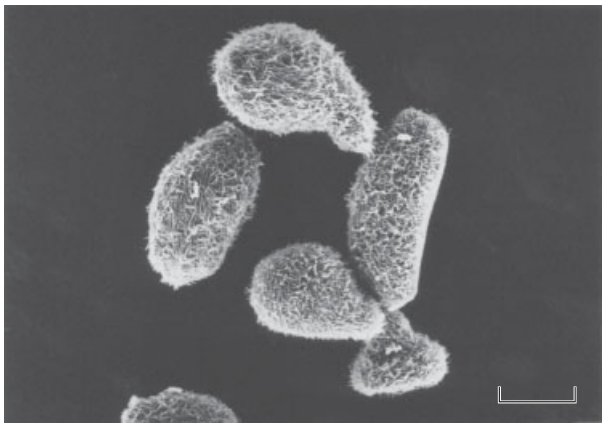

Figure 1 B. coli *trophozoites, showing variability in size and shape. SEM; bar = 30 μm*

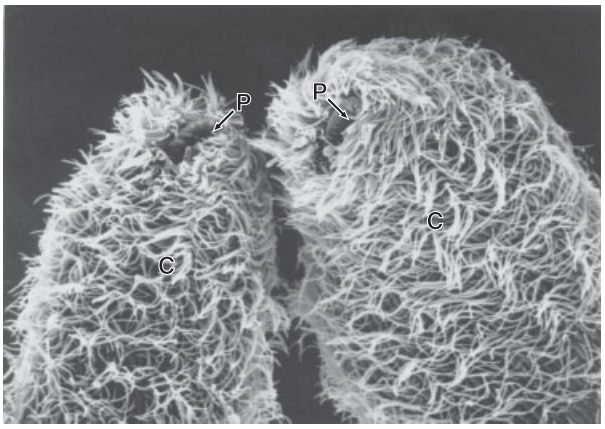

Figure 3 B. coli *trophozoites, showing peristome (P) and cilia (C) covering the body. SEM; bar = 3 μm*

anterior end of the trophozoite there is a funnel-shaped depression or mouth through which food is ingested. The mouth consists of a peristome, cytopharynx, and cytosome. The food passes from the peristome to the elongated cytopharynx and then to the cytosome. The cytopharynx, not visible when the parasite is filled with food, is often small but sometimes reaches about half the length of the parasite. The peristome appears as a rigid structure with striations when observed with the aid of a scanning electron microscope (SEM) (Figures 3 and 4).

The cilia, the organs of locomotion, cover the whole parasite and are embedded in the pellicle in longitudinal rows known as kineties. The number of kineties varies from 36 to 106 (Krascheninnikow 1962). The ciliary movement can be easily observed with the aid of a light microscope and the structure of the cilia is readily seen by SEM (Figures 3 and 4). The peristomal cilia are larger than those on the body (the somatic cilia). The peristomal cilia are used for propelling food into the cytopharynx (Figure 5). The food particles on being ingested become surrounded by a vacuolar membrane and digestion takes place inside the vacuoles. *B. coli* is capable of ingesting a variety of food particles, such as bacteria, starch grains, red blood cells, fat droplets, etc. The parasite has an excretory opening at the posterior end known as the cytopyge, which is circular and much smaller than the peristome (Figure 6).

There are two contractile vacuoles which may lie side by side or one above the other. They are easily visible to an observer using a light microscope with interference or phase-contrast capability (Figure 7). These vacuoles are responsible for maintaining the proper osmotic pressure in the cell by drawing excess water from the cytoplasm and ejecting it to the exterior.

The trophozoite has two nuclei which are clearly visible in stained preparations (Figure 8). The macronucleus, which is large and situated near the middle of the body, may be spherical, curved, elongate, or kidney shaped (Figure 9) and is enclosed in a nuclear membrane from which it can be removed intact by

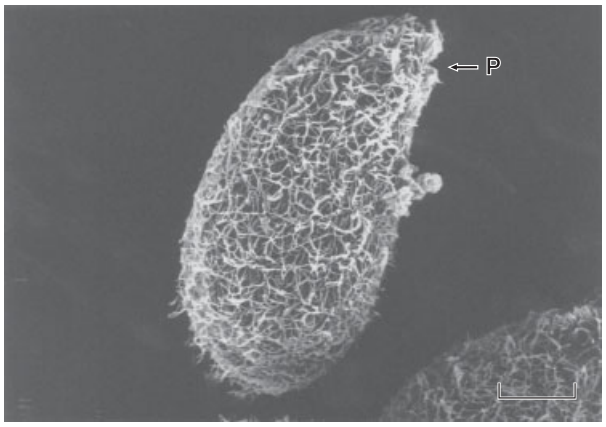

Figure 2 B. coli *trophozoite, showing peristome (P) at the anterior end. SEM; bar = 15 μm*

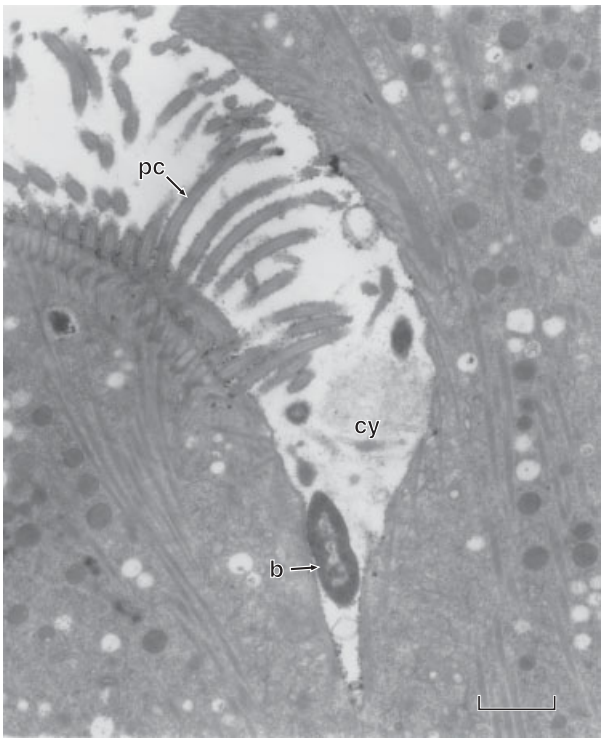

Figure 5 B. coli *trophozoite, showing peristomal cilia (pc) and cytopharynx (cy). A bacterium (b) is lying inside the cytopharynx. TEM; bar = 0.8 μm*

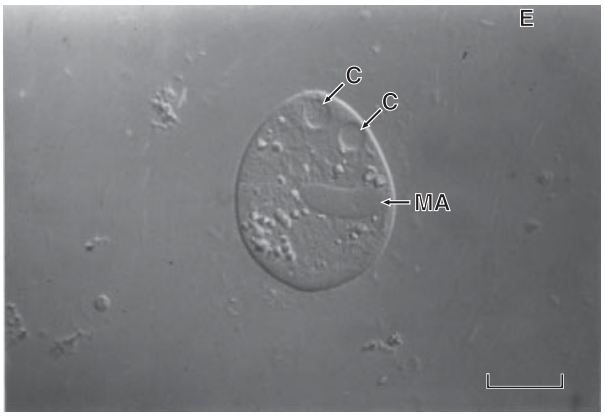

Figure 7 B. coli *trophozoite. Live organism showing macronucleus (MA) and 2 contractile vacuoles (C). Interference contrast; bar = 6 μm*

breaking the cell membrane (Figure 10). At the ultrastructural level numerous small nucleoli are visible inside the macronucleus (Figure 11). The single micronucleus is small and lies in close proximity to the macronucleus (Figures 8 and 9).

The cyst of *B. coli* is spherical to ovoid with a diameter of 40–60 μm (Figure 12). The cyst wall is thick and transparent. In electron microscopic images it is 400–500 nm thick (Figures 11 and 13). The parasite is visible inside the cyst and, in newly formed cysts, shows movement but, as the cyst matures, the cilia are absorbed and the movement ceases. The encysted stage, like the trophozoite, has a macronucleus and a micronucleus.

Life cycle

The parasite is transmitted by the oral–fecal route and the cyst is the infective stage. Excystation probably occurs in the small intestine and multiplication occurs in the large intestine.

Multiplication is by binary fission and the earliest indication of it is the elongation of the organism. Elongation is followed by the formation of a transverse structure through the middle of the body. The body gradually begins to constrict and finally separates into two daughter individuals (Figure 14). The ciliary activity continues during this process; the anterior cell develops a new excretory pore and the posterior cell a new mouth.

Sexual union (syngamy) is an important aspect of this parasite's life cycle and occurs by a process of conjugation, in which two cells come in contact with each other at their anterior ends and exchange nuclear material

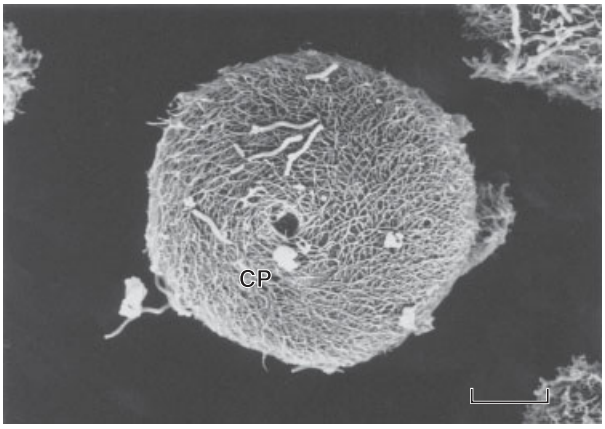

Figure 6 B. coli *trophozoite, showing the cytopyge (CP) at the posterior end. SEM; bar = 1.5 μm*

Figure 8 B. coli *trophozoite, showing macronucleus (MA) and micronucleus (MI). Trichrome stain; bar = 6 μm*

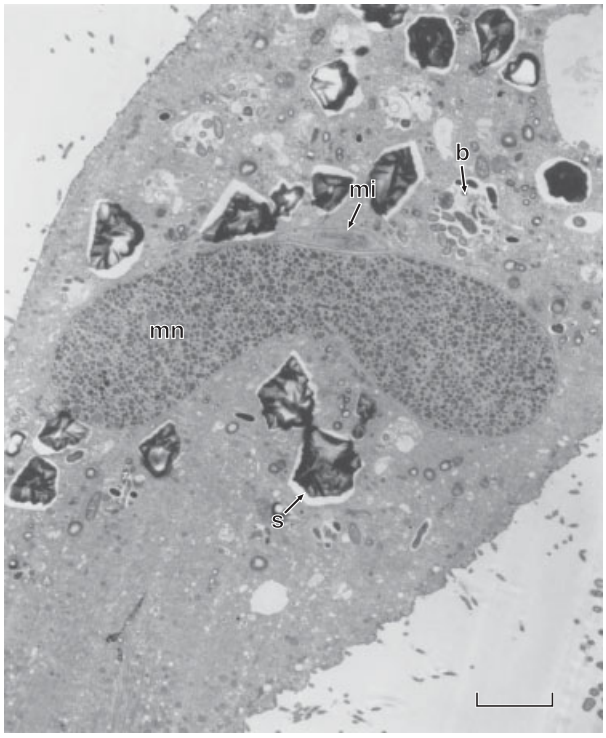

Figure 9 B. coli *trophozoite, showing the macronucleus (mn) and a small spindle-shaped micronucleus (mi). Ingested bacteria (b) and starch (s) are seen in the cytoplasm. TEM; bar = 3 μm*

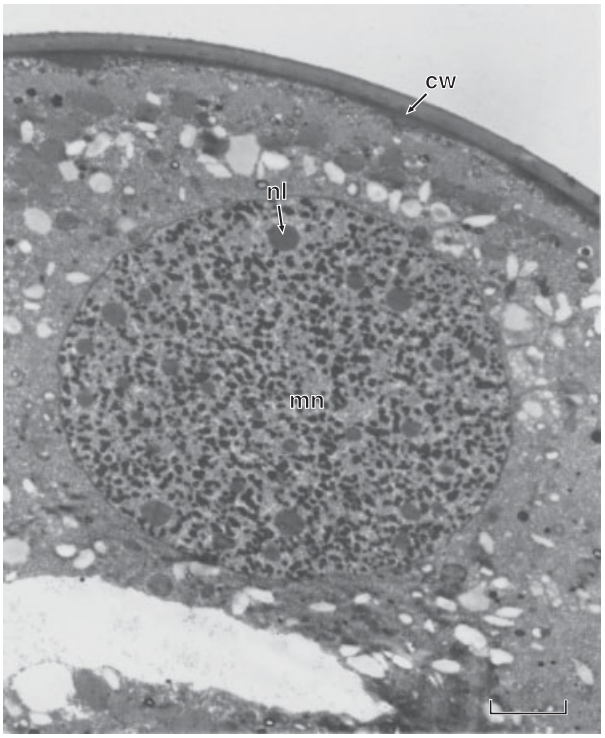

Figure 11 B. coli *cyst, showing the cyst wall (cw), macronucleus (mn) and nucleoli (nl). TEM; bar = 1 μm*

(Figure 15). Conjugation lasts for a few moments, after which the cells detach. There is no increase in numbers as a result of conjugation.

In the infected animal the parasite may be passed in the feces as a trophozoite or a cyst. The trophozoite does not encyst outside the body and disintegrates. The passed cyst survives and may contaminate food and water and may then be passed to other animals or humans. Pig-to-pig transmission is very common, and virtually 100 percent infection occurs in some piggeries where hygienic conditions are poor.

BIOCHEMISTRY

Little is known about the biochemistry of *B. coli*. Agosin and von Brand (1953) found that the ciliate is capable of consuming considerable amounts of oxygen despite the fact that it normally lives in the large intestine where little if any oxygen is available. The parasite prefers anerobic conditions, however, and in the absence of oxygen it produces a large amount of carbon dioxide. Carbohydrates are the main source of energy. Templis and Lysenko (1957) found that *B. coli* can produce hyaluronidase, which probably helps it in its invasion of

Figure 10 B. coli *trophozoite, showing the macronucleus after disruption of the cell membrane. SEM; bar = 3 μm*

the host tissues by dissolution of the intracellular ground substance.

CLINICAL ASPECTS

Asymptomatic carrier condition

Asymptomatic carriers harbor the parasites and continue to pass cysts in their feces. They are responsible for spreading infection, especially in insanitary institutional environments, such as long-stay psychiatric units.

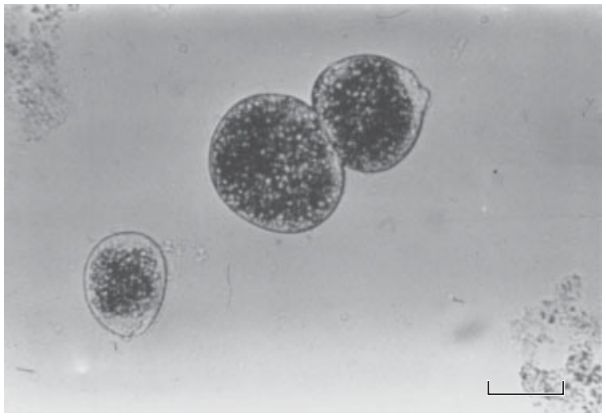

Figure 14 B. coli *undergoing binary fission. Live preparation; bar = 15 μm*

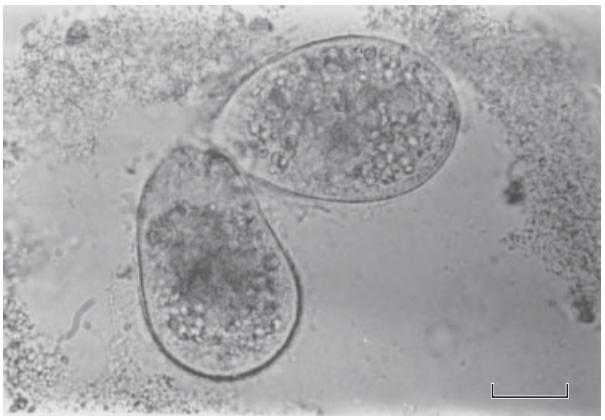

Figure 15 B. coli *undergoing conjugation. Attachment occurs at the anterior end. Live preparation; bar = 15 μm*

Chronic disease

Patients with chronic disease have periods in which frequent bowel movements alternate with periods of constipation. The feces are mucoid and rarely bloody. The organism is not easily seen in the feces and repeated stool examination may be necessary for its detection.

Acute disease

In acute disease, patients have diarrhea and the feces contain a great deal of mucus and blood (Castro et al. 1983). The clinical presentation is identical to that of acute amoebic dysentery. There may be fever and other intestinal symptoms such as anorexia, nausea, epigastric pain, vomiting, and intestinal colic. This may lead to severe dehydration, and sometimes to renal insufficiency. There is usually pain and tenderness in the cecal region. The symptoms may mimic those of appendicitis. In a majority of patients recovery occurs in 3–4 days even without treatment. In some patients, especially immunocompromised and malnourished ones, death may occur due to extensive destruction of the large intestine, involvement of the appendix, perforation, peritonitis, dehydration, and renal failure. In patients with acute infection, extraintestinal involvement such as liver abscess formation, pleuritis, and pneumonia may occur.

Immunology

There is no information about any immune responses to infection with *B. coli*. There is some evidence of age-acquired immunity in rhesus macaques where the parasite counts decrease significantly with age (Knezevich 1998). In some studies only children have been found to be infected (Devera et al. 1999), suggesting the acquisition of immunity, but this could be due to other factors such as changes in behavior. There has been a single

record of balantidial dysentery in an individual with HIV infection, and the authors suggest that the switch from asymptomatic infection to clinical dysentery might be due to immunosuppression resulting from the viral infection (Clyti et al. 1998). In this context it is interesting to note that some rhesus macaques infected with the simian immunodeficiency virus (SIV) were found to be infected with *B. coli* although the cause of diarrhea in these animals was primarily *Escherichia coli* infection (Mansfield et al. 2001). The rarity of severe human infections and the ease with which they can be cured mean that there is no need for a vaccine. The presence of conspicuous and easily identifiable cysts means that there is no need for an immunodiagnostic test.

Pathology

The gross pathologic appearance of the large intestine in patients with *Balantidium* infection is similar to that in patients with amoebiasis. On rare occasions the terminal ileum may also be infected. The gross changes consist of multiple ulcers with necrotic bases and undermined edges. The intervening mucosa may or may not be inflamed. On microscopic examination, parasites are frequently seen in clusters in the submucosa or at the bases of crypts. They can easily be recognized because of the presence of the macronucleus which stains deeply with hematoxylin and eosin (Figure 16). The cellular response is mainly lymphocytic, with some plasma cells being present. Neutrophils are few unless there is a superimposed bacterial infection. Sometimes the parasites may invade the regional lymph nodes and then they may be detected inside the lymphatic tissues. Extraintestinal balantidial infections are rare; there has been one report of *B. coli* in the bladder (Maleky 1998), but this report must be regarded with caution given our knowledge of ciliocytophthoria mentioned below.

The factors that determine whether or not *B. coli* invades the gut wall are unclear. However, in pigs, there is evidence that the presence of *Campylobacter coli* facilitates the invasion of the mucosa and both organisms seem to participate in the colitis associated with the infection (Hosino et al. 1999).

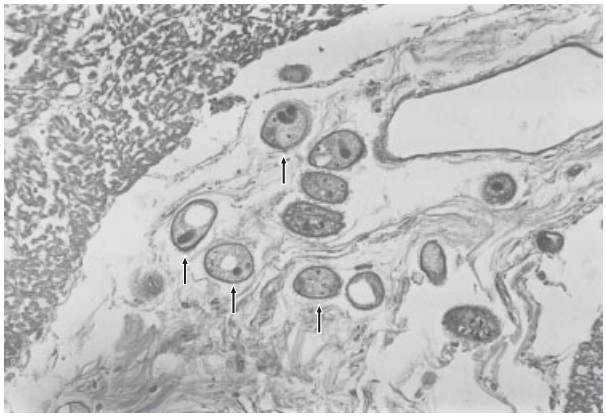

Figure 16 B. coli *in intestine. Many trophozoites (arrows) are lying in the submucosa. Hematoxylin and eosin; bar = 30 μm*

Diagnosis

Diagnosis of balantidiasis on clinical grounds is very difficult because of the nonspecific nature of the infection and possible confusion with other causes of diarrhea. Diagnosis is therefore best based on fecal examination, which reveals mainly trophozoites in acutely infected patients and cysts in patients with chronic infections. Diagnosis can also be made by the examination of biopsy specimens taken with the aid of a sigmoidoscope or by examination of scrapings of an ulcer. *Balantidium* can be cultured in all the media that support the growth of *Entamoeba histolytica* (Clark and Diamond 2002). However, culture is rarely necessary as the parasites are more easily detected in feces by microscopy and in tissues on histological examination (see Orihel and Ash 1995; Gutierrez 2000). One possible cause of confusion is the phenomenon of ciliocytophthoria resulting in normal ciliated cells appearing in unusual circumstances and there have been cases where such specimens have been tentatively identified as *B. coli* (Hadziyannis et al. 2000). These authors advocate the use of the Diff-Quik stain for the diagnosis of ciliocytophthoria.

EPIDEMIOLOGY

B. coli is worldwide in its distribution, particularly in the tropical and subtropical regions of the world including South and Central America, the Philippines, Iran, Central Asia, Papua New Guinea, and some Pacific islands. Although this ciliate is widely regarded as a common parasite of pigs that is transmissible to humans, it actually has a much broader host range and numerous surveys have shown that it occurs in a number of mammal species, both wild and domesticated. In a major survey of 297 Old World primates in Kenya, *B. coli* was detected in 6 out of 7 species with an overall prevalence of 24.9 percent (Muriuki et al. 1998). Also in Kenya, *B. coli* was found in 40 percent of 315 fecal samples from captive and wild-trapped baboons, vervets, and Sykes monkeys (Munene et al. 1998). In the New World *B. coli* was prevalent in 141 rhesus macaques in a free-ranging population (Knezevich 1998). *B. coli* is also common in camels, for example 11.9 percent of 260 fecal samples examined by Tekle and Abebe (2001) in Ethiopia and in young camels suffering from diarrhea in Bahrain (Abubakr et al. 2000). Buffaloes are also known to be infected with *B. coli*, and Patil et al. (1998) have recorded a 17 percent prevalence in 82 buffaloes suffering from diarrhea and dysentery in India. In a major survey of 567 mammalian species belonging to 17

families in Japan *B. coli* was found in 6 species of primates and artiodactyles but not in rodents, cats, or dogs (Nakauchi 1999). However, there have been occasional records of *B. coli* in dogs (Uptal Das 1999). Although there is little doubt that pigs are the main potential reservoirs of human infections, transmission to humans varies from place to place. In a survey of pigs at a Danish research farm, 57 percent of suckling pigs and 100 percent of pigs >4 weeks old were found to be infected with *B. coli*, presumably representative of this major pig-producing country as a whole, but no case of human balantidiasis has been recorded in Denmark (Hindsbo et al. 2000). In contrast, in a rural community in Venezuela, *B. coli* was detected in 33.3 percent of pigs and 12 percent of children, a situation that the authors attribute to deficient sanitation and a low socio-economic level (Devera et al. 1999). In a larger study of 2 124 children in northern Bolivia, Esteban et al. (1998) found that the overall prevalence of *B. coli* was 1.2 percent, again attributed to contact with pigs. In China the parasite appears to be endemic in Yunnan province, with infection rates of up to 4.24 percent in some villages (Yang et al. 1995). However, the highest prevalence (up to 20 percent) has been reported in the mountain districts of West Irian (Indonesia) where there is a close association between humans and pigs. McCarey (1952) has reviewed the prevalence of balantidiasis in Iran – an endemic area of unusual interest, as there is no pig farming there because of the Moslem prohibition on eating pork. The transmission was from human to human and the animal host, if any was not known; the possibility of infection acquired from camels was not considered as it was not known at that time that these acted as potential reservoir hosts.

There have been occasional sporadic outbreaks of balantidiasis in humans. A single outbreak of epidemic proportions was reported from the Pacific island of Truk (Walzer et al. 1973). It involved 110 persons in a short period of time and occurred as a result of contamination of the water supply by pig feces during a typhoon. Balantidiasis has been frequently observed in psychiatric units in the USA and many other countries. Here the transmission occurs by human-to-human contact and is due to a lack of hygienic conditions and to coprophagy.

CHEMOTHERAPY

A number of drugs, including metronidazole, secnidazole, tinidazole, tetracycline, trimethoprim plus sulfamethoxazole, sulfaguanidine, and sulfadimidine, are effective against *B. coli* in vitro (Choudhury et al. 1998), so there is no shortage of potentially useful drugs to treat humans or pigs. At present tetracycline and metronidazole are the drugs of choice for humans. Tetracycline, 500 mg, 4 times a day for 10 days, is recommended although clearance generally occurs in 2–3 days (WHO 1995). Alternatively, metronidazole, 750 mg, 3 times a day for 5–7 days, can be used but, according to WHO, results are less consistent (WHO 1995). No relapse of the infection after treatment and no resistance to these antibiotics have been reported. Treatment should be given to carriers in institutions to prevent the spread of infection to susceptible patients.

INTEGRATED CONTROL

Control consists of hygienic rearing of pigs and preventing the human–pig contact which can lead to human infections. Improved hygiene in psychiatric institutions will prevent human-to-human transmission in these settings, and treatment of humans shedding cysts will prevent human-to-human transmission. The relative lack of host specificity and close contact with other potential reservoir hosts, such as camels and buffalo, suggests that infection with *B. coli* is an ever-present problem and also that individuals working with or coming into contact with primates are at risk.

INTRODUCTION

The leishmaniases are a group of human diseases that afflict people in many tropical and sub-tropical regions. They are caused by parasitic protozoa of the genus *Leishmania* and are transmitted to humans by the bite of female phlebotomine sandflies, small blood-feeding insects. Leishmaniasis is not a single entity but a collection of diseases, each with its own clinical manifestations and epidemiology. However, the basic pattern of the life cycle is well conserved among members of the genus, and each species of *Leishmania* tends to cause a certain type of disease within a specific epidemiological context. Therefore, *Leishmania* spp. are most conveniently studied by first considering their general properties before dealing with those specific to individual species; this is the approach adopted here. Five species of *Leishmania* are the medically important agents of Old World leishmaniasis: *L. major*, *L. tropica*, *L. aethiopica*, *L. donovani*, and *L. infantum* (Figures 1 and 2).

The first three of these are predominantly agents of cutaneous leishmaniasis, an infection which is limited to the skin, and the last two are predominantly agents of visceral leishmaniasis, an infection of the liver and spleen that can be fatal. In addition to these five well-established species, a number of other named species can be found in the literature on Old World leishmaniasis. Some have subsequently turned out to be very close, if not identical, to known species; others have not been examined in sufficient detail to reach a firm conclusion with regard to their identity.

CLASSIFICATION

The genus *Leishmania*

Leishmania is one of several genera within the family Trypanosomatidae (class Kinetoplastea, order Trypanosomatida) and, therefore, shares certain properties with other members of this family described elsewhere in this volume (see African trypanosomiasis; New World trypanosomiasis). These common properties include: the possession of a kinetoplast (a unique form of mitochondrial DNA); a single flagellum arising from a flagellar pocket; and an alternation between arthropod and mammalian hosts during the life cycle.

The features that uniquely identify the genus *Leishmania* are the nature of its vertebrate and invertebrate hosts and the developmental cycles, and morphological stages found within each. The vertebrate hosts are all mammals in which the parasites reside within the phagolysosomal system of mononuclear phagocytic cells, typically macrophages (Mauel 1996; Antoine et al. 1998; Rittig and Bogdan 2000). This is a unique location for a eukaryotic parasite and is only used by a handful of prokaryotic parasites (Garcia-del Portillo and Finlay

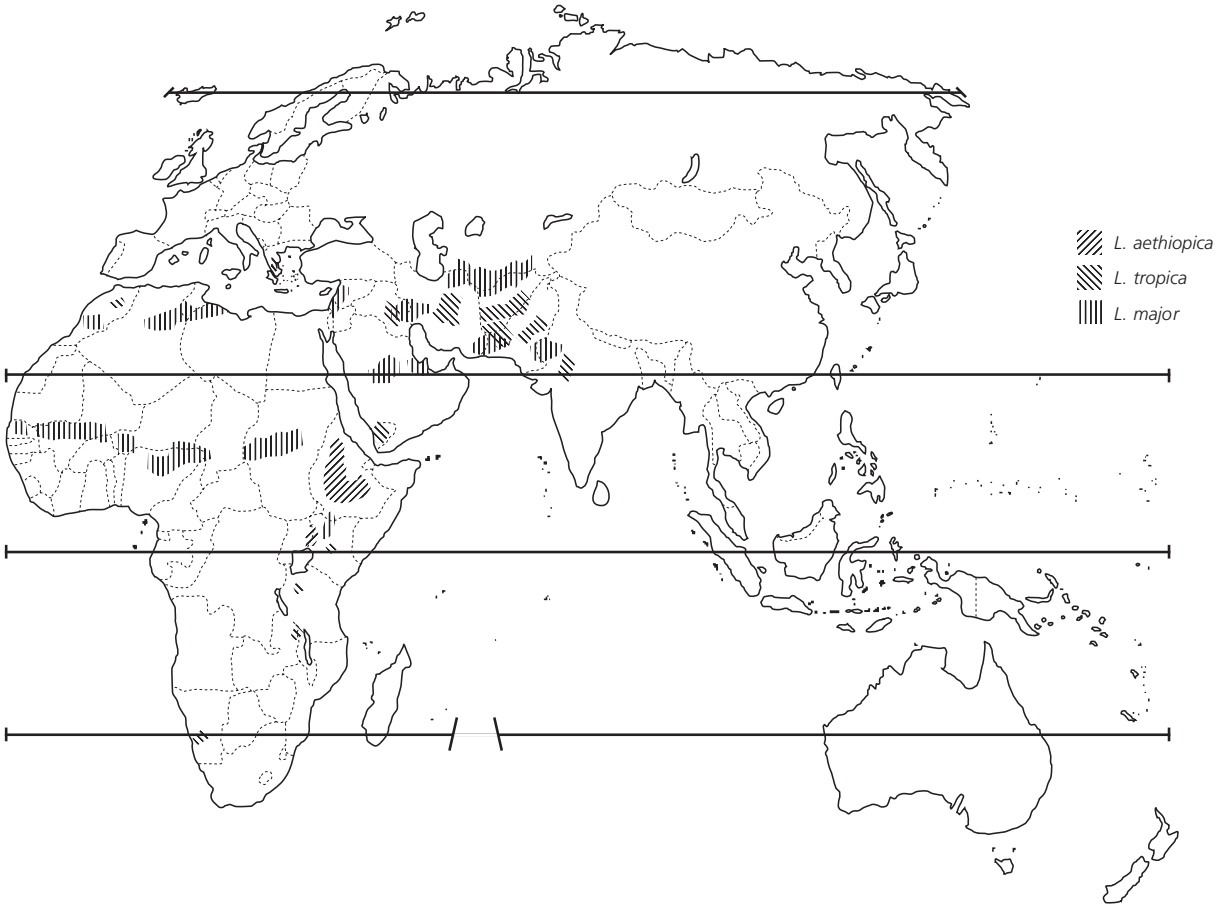

Figure 1 *Geographical distribution of the agents of Old World cutaneous leishmaniasis*

1995). The parasite gains entry to this intracellular residence via host cell phagocytosis. The invertebrate hosts are all phlebotomine sandflies of two genera; *Phlebotomus* in the Old World and *Lutzomyia* in the New World (see New World leishmaniasis). These are small, hairy, dipteran flies of the family Psychodidae, in which only the females feed on blood and transmit disease. In the sandfly, the parasites are extracellular; development occurs exclusively in the gut and transmission is via the mouthparts during blood feeding (reviewed by Schlein 1993; Walters 1993; Bates 1994a; Sacks and Kamhawi 2001).

Various taxonomic distinctions have been proposed at the subgeneric, species, and subspecies levels, but at present there is no generally accepted classification that incorporates all of these elements. Here, we adopt a conservative pragmatic approach, essentially following Lainson and Shaw (1987), but without any subgeneric or subspecific qualifiers. In *Leishmania* the biological species concept of a population of potentially interbreeding individuals cannot be applied, as the genus seems to be largely, if not exclusively, asexual in its mode of reproduction (Victoir and Dujardin 2002). The ideal classification for an asexual organism at the level of the 'species' combines the maximum biological homogeneity within each species, but separates biologically different organisms. Among the techniques available for the classification of *Leishmania*, isoenzyme analysis has been found to describe strains at a level that allows the construction of phenograms and cladograms at an ideal resolution (Rioux et al. 1990). Using a panel of c. 12 enzymes, it is possible to identify and distinguish most, but not all of the currently accepted species (Jamjoom et al. 2004). The group of strains that share a given pattern of enzyme electrophoretic mobilities are known as a 'zymodeme'. A given species may contain a number of zymodemes indicating subpopulations or subspecies. There has been an enormous accumulation of data using this method; it has largely confirmed what was known or expected biologically but has also provided valuable new insights, such as the fact that cutaneous leishmaniasis in Europe is caused by *L. infantum*. An example of a cladogram constructed using isoenzyme data is shown in Figure 3. The main disadvantage of isoenzyme analysis is the lack of standardization between laboratories; the importance of the strictest laboratory protocols to prevent mixing of cultures cannot be overemphasized.

Of the other techniques that have been used, the resolution of restriction fragment length polymorphisms

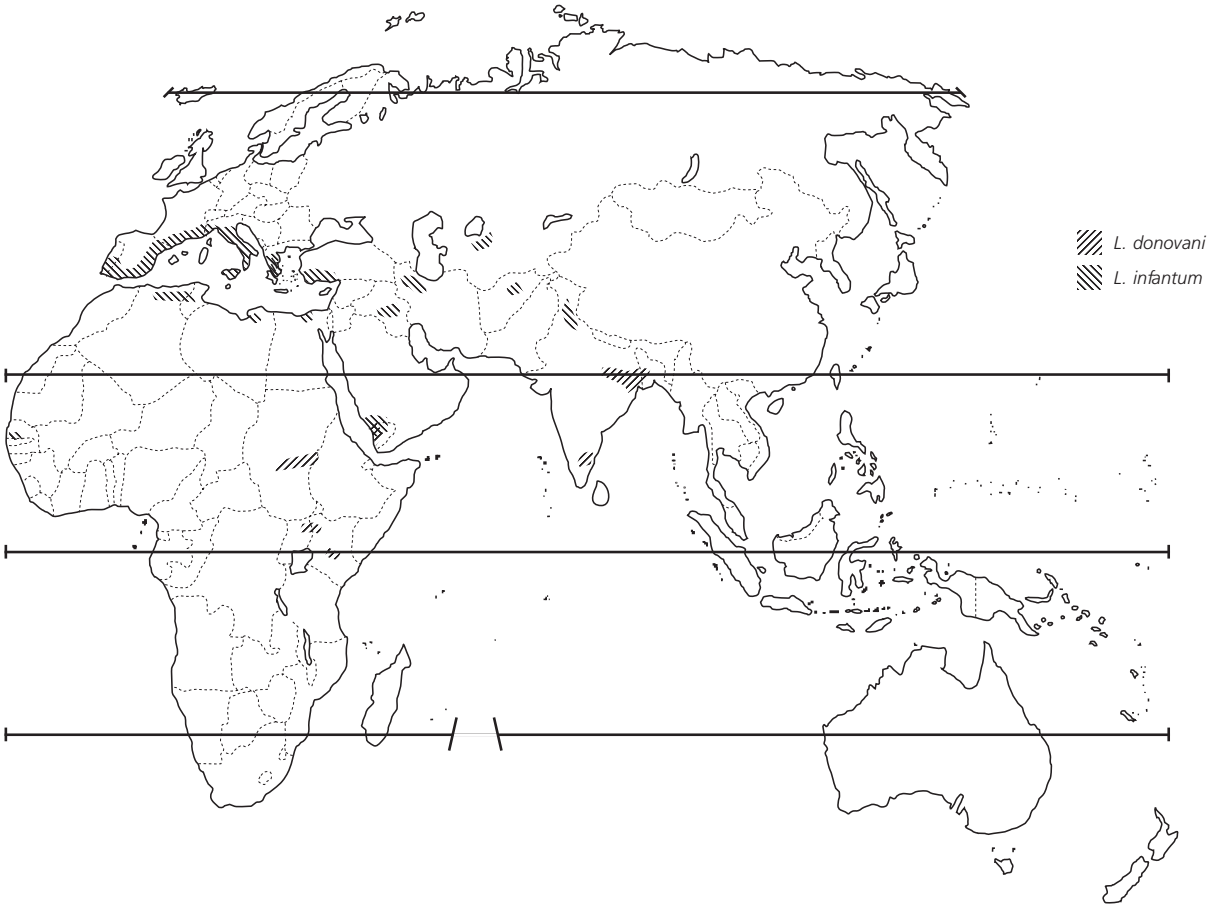

Figure 2 *Geographical distribution of the agents of Old World visceral leishmaniasis*

(RFLP) and karyotype analysis has been found to be too fine except for studies at the population genetic level. Microsatellite DNA analysis is the latest technique being used with *Leishmania* and seems well suited to resolving taxonomic issues at the infraspecific level (Bulle et al. 2002; Jamjoom et al. 2002). DNA and ribosomal RNA sequence information hold much promise and have given valuable results at the generic level and above, but have not been sufficiently widely used yet to contribute to classification at the species level. Monoclonal antibody and DNA probes, with or without polymerase chain reaction (PCR) amplification, are of value in identification of stocks that have been well classified, but provide insufficient information to be of value in constructing a classification. A disadvantage of most current methods is the requirement to culture the parasite in question before identification can be made.

Of the five species considered in this chapter, all are distinct from those found in the New World (see New World leishmaniasis) with one important exception, *L. infantum*. Molecular analysis reveals this to be indistinguishable from *L. chagasi* found in the New World (Mauricio et al. 1999, 2000). Because the former was named first both parasites should be referred to as *L. infantum*. We favor the explanation that '*L. chagasi*' is, in fact, *L. infantum* that was introduced into the New World in post-Columbian times via the domestic dog (Momen et al. 1993; Courtenay et al. 2002). While others may disagree with this interpretation, it is certain that these two parasites are very closely related. The remaining New World parasites have rather different biology, clinical manifestations, and epidemiology to those of the Old World and are dealt with separately in New World leishmaniasis. The main features of the Old World species are summarized in Table 1.

STRUCTURE AND LIFE CYCLE

The parasite exists in two main morphological forms, 'amastigotes' and 'promastigotes', found in the mammalian and sandfly hosts, respectively. Amastigotes are ovoid, non-motile, intracellular stages; promastigotes are elongated, motile, extracellular stages. The form introduced into the skin of the mammalian host is a promastigote, but this soon transforms into an amastigote, and the parasite remains in this form for the duration of the mammalian phase of the life cycle. Similarly, the form taken up by the sandfly is an amastigote, but this soon transforms into a promastigote. The basic life cycle of

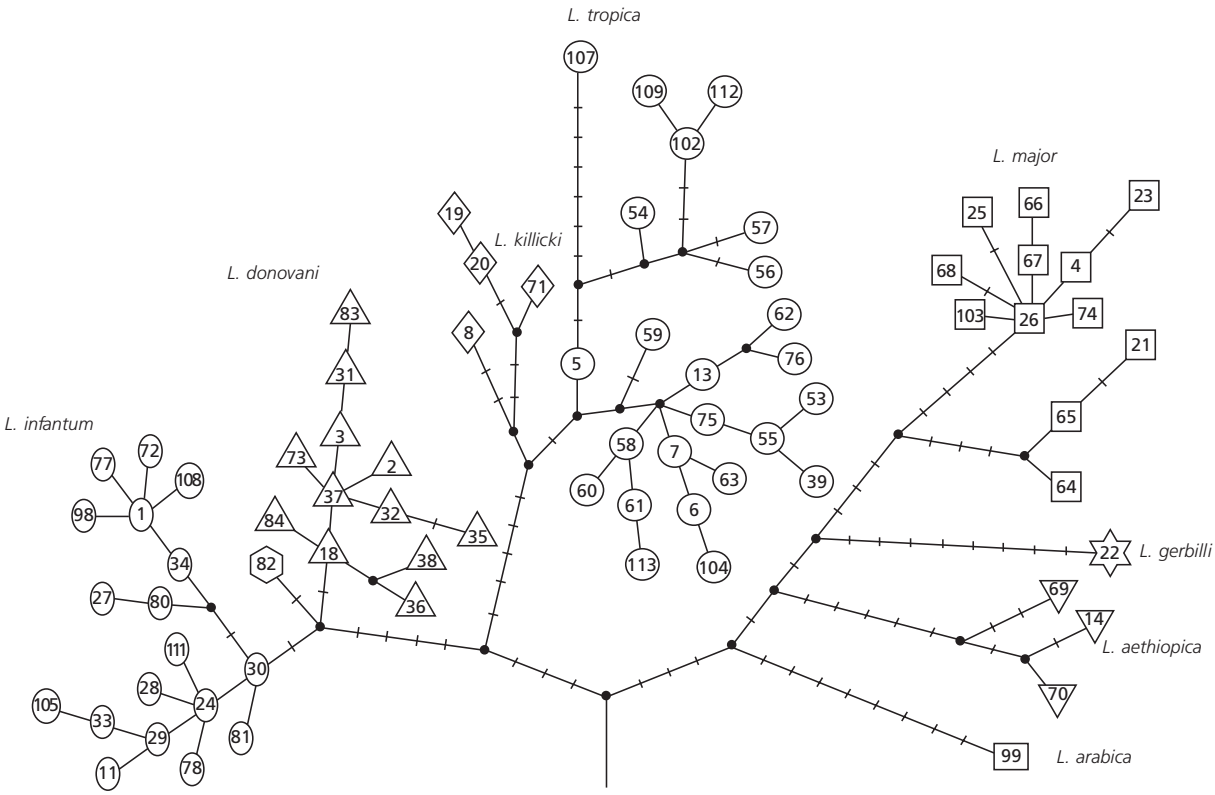

Figure 3 *Cladogram of Old World* Leishmania *zymodemes showing grouping into 'species'.* L. gerbilli *and* L. arabica *are not known from humans. (Modified from Rioux et al. 1990)*

Leishmania is illustrated in Figure 4 (reviewed by Molyneux and Killick-Kendrick 1987).

Amastigote structure

Amastigotes are ovoid cells of 3–5 μm length on the main axis and, therefore, lie at the lower limit of size described for eukaryotic cells. Because of their small size, little internal structure can be discerned in stained preparations at the light microscope level beyond the central round or oval nucleus and adjacent but smaller round or rod-shaped kinetoplast. At the ultrastructural level, more detail is revealed (Figure 5). The surface membrane is a conventional unit membrane under which lies a corset of microtubules, serving as a form of cytoskeleton. These are closely spaced in parallel rows

Table 1 *Summary of the main features of Old World* Leishmania *species*

Species	Disease in humans	Geographical distribution	Important mammalian hosts	Important sandfly hosts
L. major	Rural, zoonotic, cutaneous leishmaniasis, oriental sore	North Africa, Sahel of Africa, Central and West Asia	Great gerbil *Rhombomys opimus*, fat sand rat *Psammomys obesus*	*Phlebotomus papatasi*, *P. dubosqi*, *P. salehi*
L. tropica	Urban, anthroponotic cutaneous leishmaniasis, oriental sore	Central and West Asia	Humans	*Phlebotomus sergenti*
L. aethiopica	Cutaneous leishmaniasis, diffuse cutaneous leishmaniasis	Ethiopia, Kenya	Rock hyraxes *Heterohyrax brucei* and *Procavia* spp.	*Phlebotomus longipes*, *P. pedifer*
L. donovani	Visceral leishmaniasis, kala-azar, post kala-azar dermal leishmaniasis	Indian subcontinent, East Africa	Humans	*Phlebotomus argentipes*, *P. orientalis*, *P. martini*
L. infantum	Infantile visceral leishmaniasis	Mediterranean basin, Central and West Asia	Domestic dog	*Phlebotomus ariasi*, *P. perniciosus*

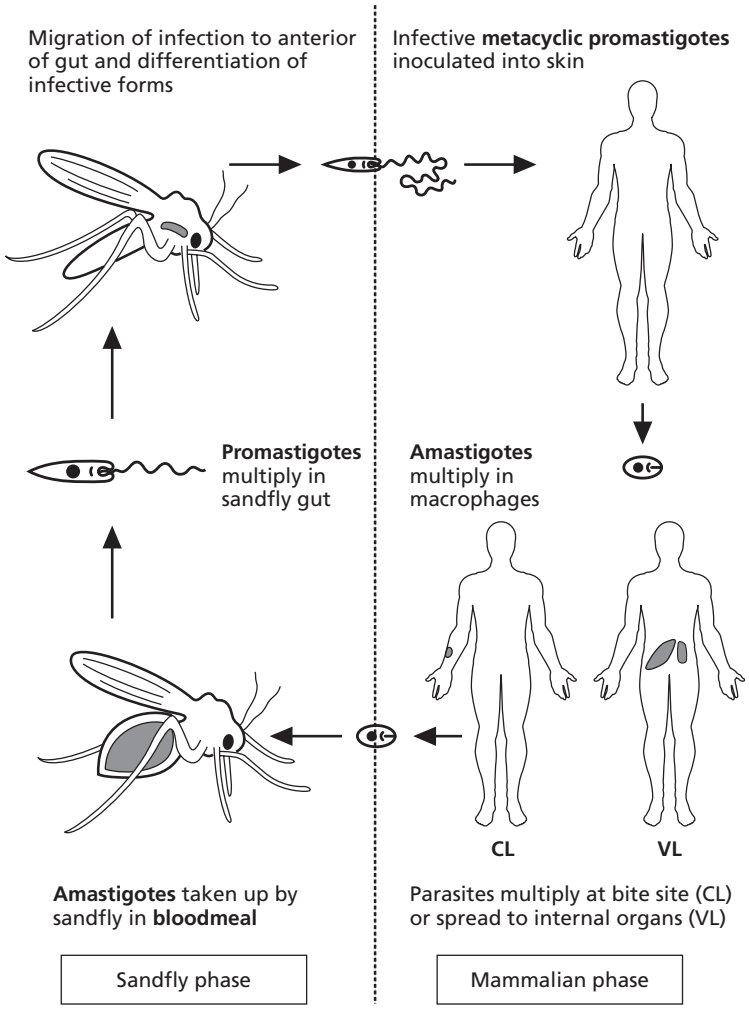

Figure 4 *General life-cycle of* Leishmania. *Parasites alternate between sandfly and mammalian hosts, existing as promastigote and amastigote forms, respectively. Mammalian infection results in cutaneous leishmaniasis (CL) or visceral leishmaniasis (VL).*

which, together with the small size, make the amastigote a very robust eukaryotic cell. One unfortunate consequence of this feature is that it has not proved possible to develop subcellular fractionation techniques for amastigotes that will disrupt the surface membrane without destroying the organelles contained within. On the positive side, fairly vigorous homogenization techniques can be employed for the isolation of amastigotes from infected tissue without destroying their viability or structural integrity.

An infolding of the surface membrane creates an internal space, termed the 'flagellar pocket' (Webster and Russell 1993; Landfear and Ignatushchenko 2001). This is so named because a flagellum emerges from the surface membrane and projects into the pocket. This flagellum is not functional in the amastigote and does not extend beyond the cell body. The flagellar pocket is thus topologically external to the cell although contained within it. In addition to anchoring the flagellum, the main function of the pocket is as a site of endocytosis and exocytosis (McConville et al. 2002; Morgan et al. 2002). Microtubules do not underlie the surface of the flagellar pocket membrane thus allowing access to vesicular traffic. Immediately below the origin of the flagellum lies the kinetoplast, a dense mass of mitochondrial DNA. The kinetoplast DNA is composed of several thousand circular DNA molecules linked together in a catenated network (Shlomai 1994; Shapiro and Englund 1995; Lukes et al. 2002). The DNA circles are of two size classes: each kinetoplast contains 25–50 maxicircles of c. 30 kb, and 5000–10 000 minicircles of c. 2 kb. Together these constitute the mitochondrial genome. Branches of the surrounding mitochondrion extend throughout the cell body and contain plate-like cristae.

The cytoplasm contains both rough and smooth endoplasmic reticulum. The Golgi apparatus is typically found in the vicinity of the flagellar pocket, which probably reflects the role of this organelle in the endocytic and exocytic pathways. Lysosomes are also found in the cytoplasm together with an organelle unique to kinetoplastids, the glycosome. This is so named because a

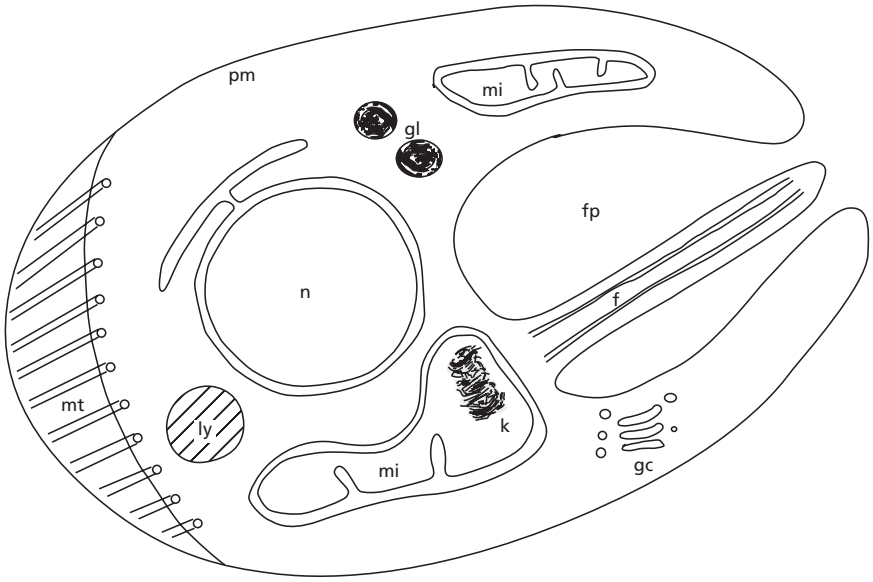

Figure 5 *Ultrastructure of a* Leishmania *amastigote. Amastigotes possess a central nucleus (n) and adjacent kinetoplast (k) within a single branching mitochondrion (mi). The flagellum (f) arises from a flagellar pocket (fp) but does not extend beyond the cell body. Lysosomes (ly), glycosomes (gl) and Golgi complex (gc) are found in the cytoplasm. Rows of microtubules (mt) run just below the plasma membrane (pm).*

number of glycolytic enzymes are specifically located in this organelle, together with some others (Michels et al. 1997; Parsons et al. 2001).

Promastigote structure

In the sandfly host, the parasite is found mainly as a promastigote form (Figure 6). The structural elements of promastigotes are the same as those described for amastigotes although there may be variations in organelle numbers. The main differences from the amastigotes are that the cell body is elongated, 8–15 μm, and that the flagellum emerges from the cell body and is functional thus making these motile cells. The flagellum is found at the anterior end of the cell, i.e. the cell body is trailed behind the flagellum. Desmosomal plaques anchor the flagellum to the cell body as it emerges from the flagellar pocket. The promastigote flagellum has a paraxial rod, a paracrystalline structure running parallel to the microtubules of the axoneme, which plays a role in flagellar motility (Maga et al. 1999). Recently, a novel tubular lysosome that is part of the endocytic pathway has been described in promastigotes (Waller and McConville 2002).

Life cycle

DEVELOPMENT IN THE SANDFLY HOST

The phase of the life cycle in female sandflies is of relatively short duration. Flies that acquire a *Leishmania* infection probably remain infected for life, but this is

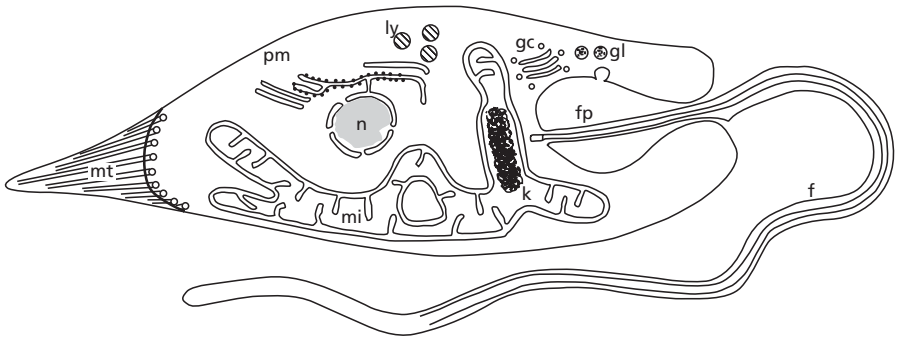

Figure 6 *Ultrastructure of a* Leishmania *promastigote. Many of the features found in the amastigote stage are also found in the promastigotes (abbreviations, see Figure 5). Some differences are that the cell body is elongated, the flagellum extends beyond the cell body and the kinetoplast has a more anterior location relative to the nucleus.*

usually only a matter of weeks. In most parasite–vector combinations that have been studied experimentally, the development of the parasite is sufficiently rapid for mammal-infective promastigotes to be produced by the time the female is ready to take her next bloodmeal. This may be as little as 5–7 days under optimal conditions. Development occurs exclusively in the sandfly gut (Figure 7) and begins with infected macrophages or free amastigotes in the bloodmeal. The macrophages disintegrate over a matter of hours and, as with the mammalian phase, the first event is transformation, in this case to the promastigote form, which takes 24–48 h. Promastigotes of various kinds grow and divide in the sandfly gut. The ultimate products of the developmental cycle are the mammal-infective forms, termed 'metacyclic promastigotes', which accumulate in the anterior midgut and foregut of the sandfly.

The developmental cycle of *Leishmania* in the sandfly host is illustrated in Figure 8 and reviewed in Bates and Rogers (2004). Promastigote development has been studied using a variety of combinations of parasite and vector (Killick-Kendrick 1990a; Walters 1993; Bates 1994a) and two patterns have emerged for those species infective to mammals. Certain species usually include a phase of development in the hindgut of the sandfly, for example the New World species *L. braziliensis*, share certain other features, and form a distinct cluster of species according to isoenzyme and DNA sequence analysis. These exclusively New World species are placed in a separate subgenus, (*Viannia*) and are described in detail in New World leishmaniasis. The majority of *Leishmania* species, including all the Old World parasites, in which there is no hindgut development are placed in another subgenus (*Leishmania*).

There are a variety of different promastigote forms that can be distinguished on morphological grounds and various authors refer to these by different names, often interchanging cultured and sandfly-derived promastigotes. However, the evidence for functional distinction is less complete. In the Old World *Leishmania* species, six developmental forms are recognized during development: procyclic promastigotes, nectomonad promastigotes, leptomonad promastigotes, haptomonad promastigotes, paramastigotes, and metacyclic promastigotes (Rogers et al. 2002; Gossage et al. 2003; Figure 9). Other categories and subdivisions can be found in the literature, but at present there is little evidence for any functional distinction between them.

The first major developmental event in the sandfly is the transformation of amastigotes to procyclic promastigotes. However, very few observations on the early events have been made and it is also possible that some amastigotes may divide before transforming to promastigotes. Amastigote to promastigote transformation occurs readily in vitro and is usually completed in 24–48 h when

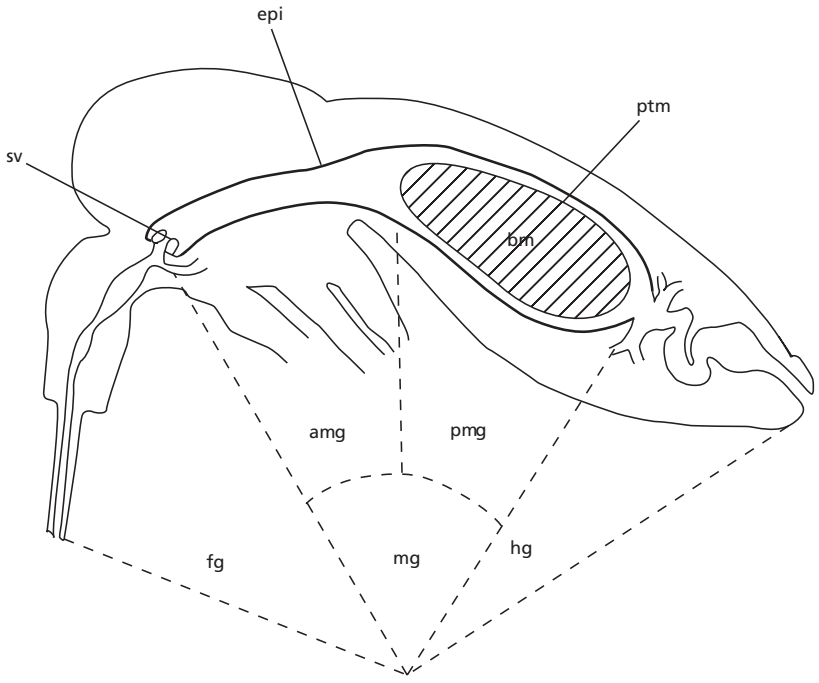

Figure 7 *Structure of the female sandfly gut. The gut can be subdivided into three sections: the foregut (fg), midgut (mg), and hindgut (hg). The midgut is lined by epithelial cells (epi) with microvilli that project into the lumen of the gut and is subdivided itself into the anterior or thoracic midgut (amg) and the posterior or abdominal midgut (pmg). The junction between the anterior midgut and the foregut is formed by the stomodeal valve (sv). The foregut, stomodeal valve and hindgut are lined by a chitinous cuticular layer. Initial development of the parasite occurs within the bloodmeal (bm) encased in a peritrophic matrix (ptm) in the posterior midgut.*

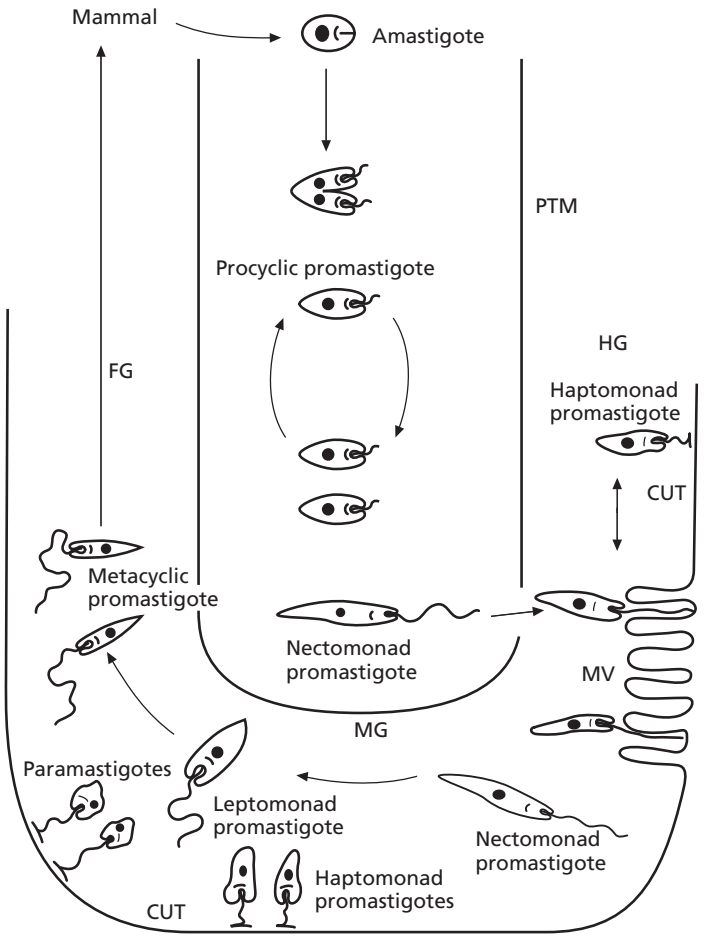

Figure 8 *Developmental cycle of* Leishmania *promastigotes. Amastigotes are ingested by a female sandfly and transform to procyclic promastigotes in the bloodmeal, itself encased in a peritrophic matrix (PTM) in the midgut (MG). Procyclic promastigotes are gradually replaced by nectomonad promastigotes that escape from the ptm; some attach to the microvilli (mv) via their flagella. In some species, haptomonad forms attach to the cuticular lining (cut) in the hindgut (HG), in others they attach in only the foregut (FG) and stomodeal valve. Paramastigotes may also be found in the foregut. Leptomonad promastigotes multiply in the anterior midgut and differentiate into metacyclic promastigotes to complete the developmental cycle.*

a suitable culture medium and an appropriate temperature (about 26°C) is used. The media used vary widely, but the optimal pH for promastigote growth, and that used in culture media, is generally neutral to slightly alkaline (pH 7.0–7.5). In vitro transformation to promastigotes and cell division occur coincidentally, such that, of the first forms observed in division, the majority are partially transformed intermediates (Bates 1994b). The signals initiating both processes may be the same and it is possible that they are mechanistically linked.

In the sandfly, these events occur in the posterior midgut in the bloodmeal that is itself encased in a peritrophic matrix (PTM) secreted by the midgut epithelium. The PTM is a lattice of chitin fibrils, proteins and glycoproteins secreted by the midgut epithelium in response to a bloodmeal (Shao et al. 2001). In phlebotomine sandflies, the PTM is produced at one time and encapsulates the whole bloodmeal offering some protection to the parasite during amastigote to procyclic promastigote transformation by limiting their exposure to trypsin secreted by the midgut epithelium (Pimenta et al. 1997). This temporary vulnerability to trypsin is probably a result of reorganization of the surface glycocalyx during transformation. The procyclics are short, ellipsoid promastigotes generally about 6–8 μm in body length. Multiplication of procyclic promastigotes occurs within the PTM but gradually the promastigotes elongate and transform to nectomonad forms of 15–20 μm body length.

Approximately 3 days after blood feeding, the PTM usually begins to break down and promastigotes begin to

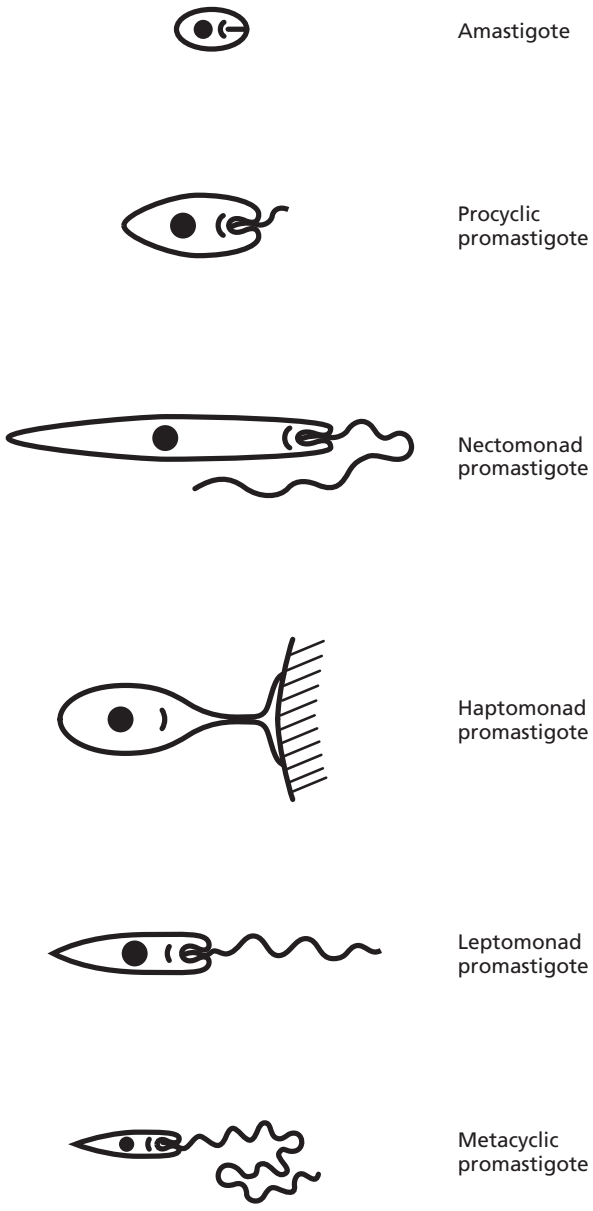

Figure 9 *Promastigote developmental forms (after Rogers et al. 2002). The six main morphological stages found in the life-cycle of* Leishmania *drawn to show their relative sizes and shapes.*

migrate forward to the anterior midgut. There is evidence for an accelerated breakdown of the PTM in infections of *L. infantum* in *Lutzomyia longipalpis* (Walters 1993) and *L. major* in *Phlebotomus papatasi* (Schlein et al. 1991). One explanation for this phenomenon is the presence of a chitinase secreted by promastigotes (Schlein et al. 1991; Shakarian and Dwyer 1998, 2000). This is presumed to have survival value to the parasite as it would permit establishment of a midgut infection outside the PTM earlier than would otherwise be the case. In some vectors, it could be essential for escape from the PTM before defecation of the bloodmeal remnants by the sandfly.

The transformation from procyclics to nectomonads can be mimicked in vitro (Bates 1994b). In this study, lesion amastigotes were allowed to transform, procyclics appeared on day 2 and, after 3 days of growth, a population consisting predominantly of nectomonad forms was obtained. The timing of these events is strongly reminiscent of the situation in sandfly infections and occurs in vitro at a particular growth phase (late exponential phase). The latter suggests that transformation to nectomonads is a density-dependent phenomenon and could be triggered, for example, by a factor such as nutrient depletion. This could be a useful adaptation in vivo as the initial source of nutrition, the bloodmeal, becomes exhausted. Charlab and Ribeiro (1993) found that inhibition of growth by exposure of promastigotes to salivary gland homogenate from *Lu. longipalpis* caused transformation to nectomonads in vitro. Whether parasites are exposed to sandfly saliva during their development in the midgut is uncertain, but is a possibility after escape from the PTM. Flies continue to take sugar meals over the several days that the bloodmeal is being digested and as promastigote development occurs.

Some of the nectomonads attach to the midgut epithelium, inserting their flagella between the microvilli (Killick-Kendrick 1990a). The major surface glycolipid of promastigotes, lipophosphoglycan (LPG) (Turco and Descoteaux 1992), mediates this attachment, which is important for establishment of a mature infection, i.e. one that persists beyond the initial multiplicative phase in the bloodmeal (Lang et al. 1991; Pimenta et al. 1992, 1994). Binding of promastigotes to dissected midguts in vitro can be inhibited by free LPG or its constituents and there is a positive correlation between the binding of LPG isolated from a particular parasite to dissected midguts of sandflies, and the ability of the given vector to transmit that parasite (Pimenta et al. 1994; Sacks et al. 1994; Sacks 2001). Mutants specifically unable to express LPG cannot attach to the midgut and maintain an infection in sandflies (Sacks et al. 2000).

LPG covers the entire surface including the flagellar membrane where it could mediate binding (Lang et al. 1991). However, one unexplained feature of midgut attachment is the striking feature of flagellar insertion, a phenomenon restricted to the subgenus *Leishmania*. The reason may be that the juxtaposition of elongated flagella and microvilli provides a good fit that maximizes the number of binding sites and hence, with time, the promastigotes will adopt this orientation. However, it is premature to discount the possibility that other flagellar-specific molecules could be involved and provide additional specificity.

By 5 days, the infection has usually spread to the anterior midgut and the cuticular surface of the stomodeal valve at the junction with the foregut. Nectomonad forms are responsible for this anterior migration and, upon reaching the anterior midgut, give rise to leptomonad promastigotes and haptomonad promasti-

gotes (Rogers et al. 2002). Leptomonad forms, promastigotes of 6-8 μm, accumulate in the lumen of the midgut producing a gel-like substance, promastigote secretory gel (PSG) (Stierhof et al. 1999; Rogers et al. 2002). Haptomonad forms, broad cells of 5–8 μm, are found attached to the stomodeal valve via hemidesmosomes in expansions of their flagellar membranes (reviewed by Vickerman and Tetley 1990). The PSG produced by leptomonad forms and the attached haptomonads both assist with transmission by helping to create a 'blocked fly' (see below). Attached paramastigotes (nucleus adjacent to kinetoplast) and haptomonads may also be found in the foregut. In these attached forms, the flagellar membrane can be seen at the ultrastructural level to be closely apposed to the surface forming a junctional complex. An electron-dense plaque and associated filaments are located below the flagellar membrane, and thus these attachment organelles bear a superficial resemblance to the hemidesmosomes found at the basal surfaces of vertebrate epithelial cells.

From day 5 onwards, increasing numbers of small (5–8 μm), narrow, highly motile, metacyclic promastigotes, the mammal-infective forms, can be observed in the lumen of the anterior midgut and/or foregut in a position that facilitates their transmission on subsequent blood feeding by the female sandfly. Metacyclics differentiate from leptomonad promastigotes (Rogers et al. 2002), a process that can be induced in vitro by culture at low pH (Bates and Tetley 1993; Zakai et al. 1998), under anaerobic conditions (Mendez et al. 1999), or nutrient depletion (Cunningham et al. 2001). Conversely, both metacyclogenesis and chitinase secretion by *L. major* are inhibited by the inclusion of hemoglobin in the culture medium (Schlein and Jacobson 1994a). Unlike the other transformations described so far, this is more properly described as a differentiation process, as the end-product is in a non-dividing state.

TRANSMISSION FROM SANDFLY TO MAMMALIAN HOST

The opportunity for transmission from an infected sandfly to a mammalian host occurs when the fly is ready to take another bloodmeal. There is debate concerning the precise mechanisms that aid transmission and the extent to which the parasites themselves contribute to this process; these may vary with the specific vector–parasite combination. For the parasites to become lodged in the skin of a mammal, they must travel against the predominant flow of blood, which is into the gut of the fly.

In a sandfly containing a mature infection, the majority of promastigotes are found in the anterior midgut with a smaller population in the foregut. The number of promastigotes required to initiate a mammalian infection varies between hosts and parasite/vector combinations; the numbers inoculated are believed to be in the range 10–1 000 metacyclic promastigotes per infective bite (Rogers et al. 2004).

Under experimental conditions, infected flies show differences in feeding behavior when compared to uninfected flies. Frequently, they are seen to probe the skin an increased number of times and appear to find difficulty in taking a bloodmeal, a behavior that may enhance transmission (reviewed by Molyneux and Jeffries 1986; Molyneux and Killick-Kendrick 1987). Massive infections develop in and block the anterior midgut of both experimentally infected and wild-caught flies, with the promastigotes embedded in PSG (Stierhof et al. 1999; Rogers et al. 2002). The main component of PSG is a mucin-like filamentous proteophosphoglycan (Stierhof et al. 1999; Ilg 2000). Haptomonad forms attached to the stomodeal valve and foregut also contribute to the blockage of the gut. The parasite/gel plug appears to form a physical obstruction to feeding, a so-called 'blocked fly', resulting in an increased frequency of multiple probing and failed attempts to engorge.

During sandfly feeding, infective metacyclic promastigotes are carried out along with sandfly saliva and PSG (Rogers et al. 2004). Both saliva and PSG can enhance the infectivity of the promastigotes in the mammalian host (Titus and Ribeiro 1990; Belkaid et al. 1998; Kamhawi 2000; Rogers et al. 2004). Anti-saliva immune responses may be a useful component of anti-leishmanial vaccines (Kamhawi et al. 2000). Much debate has centered on the position and the types of promastigote found in the foregut and midgut: specifically where the mammal-infective forms are found (Killick-Kendrick 1990a). The two main ideas proposed are that metacyclic promastigotes are directly inoculated from the proboscis (the anterior part of the foregut), or regurgitated forward from more distal parts of the foregut and possibly the midgut. The current consensus favors regurgitation as the main mode of transmission, and this has been recently proven in *L. mexicana*-infected sandflies (Rogers et al. 2004). A variation on simple regurgitation comes from observations that the stomodeal valve can be damaged and remain permanently open as a result of the parasite infection, as has been described with infections of *L. major* in *Phlebotomus papatasi* (Schlein et al. 1992). Where such damage does occur, it may permit mixing of the contents of the anterior midgut with an incoming bloodmeal, such that when the pharynx contracts to deposit blood in the midgut, there is also a forward surge of promastigote-contaminated blood into the wound.

DEVELOPMENT IN THE MAMMALIAN HOST

The developmental cycle of *Leishmania* in the mammalian host is illustrated in Figure 10. This cycle is initi-

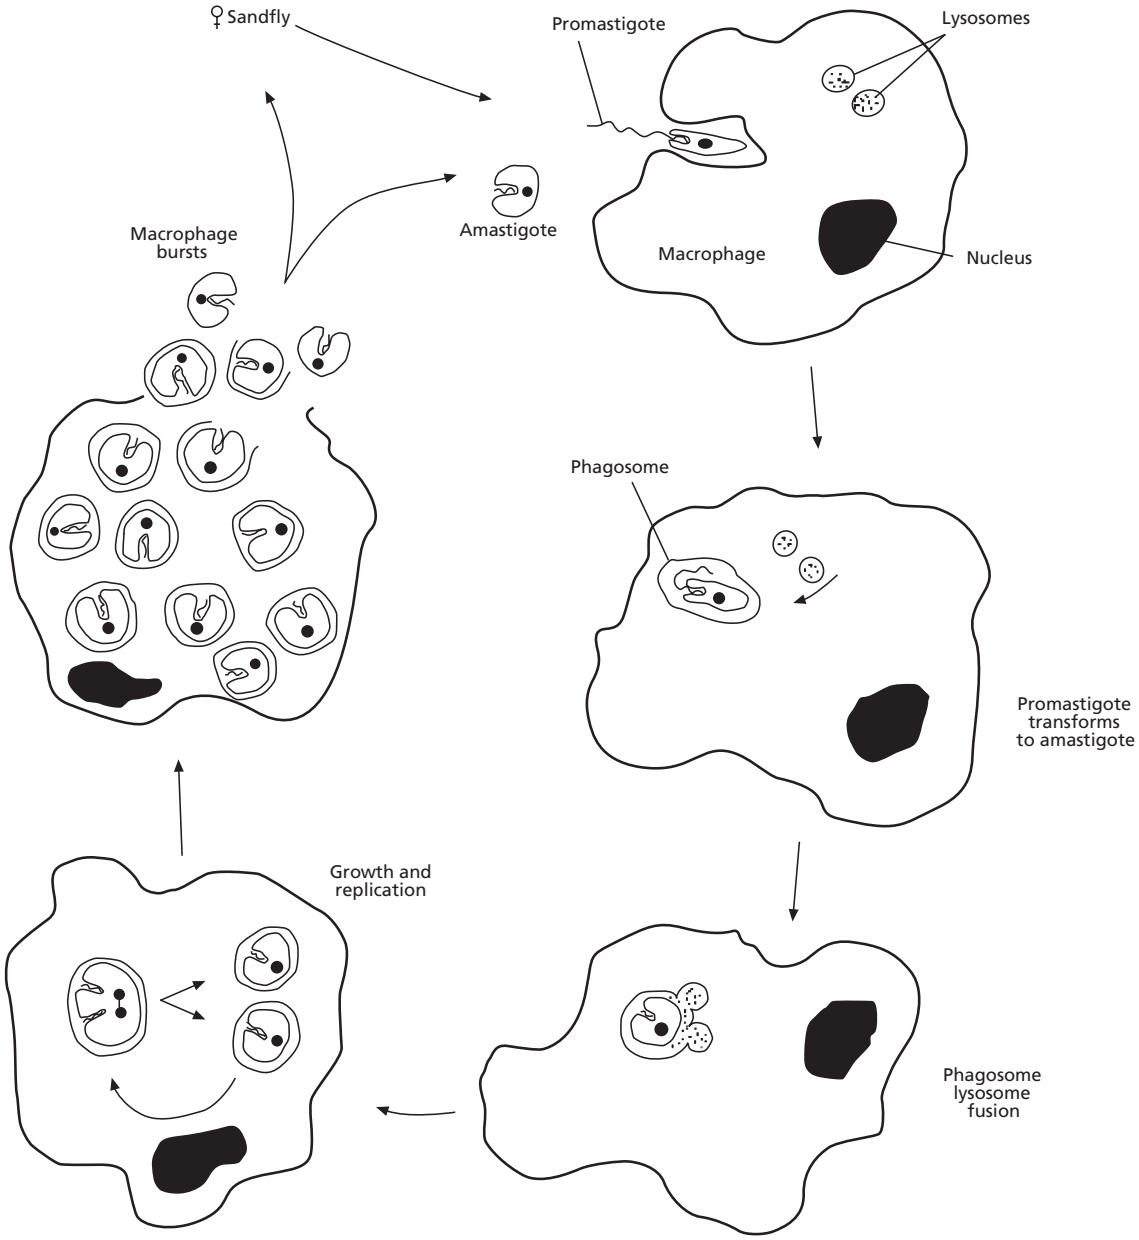

Figure 10 *Developmental cycle of* Leishmania *amastigotes*

ated by the interaction of metacyclic promastigotes with skin macrophages. The precise kinetics of parasite transformation and uptake by skin macrophages is uncertain, but it is generally assumed that uptake occurs soon after inoculation and that the promastigote to amastigote transformation occurs mainly inside the host cell. Direct studies on the binding and uptake of metacyclics by skin macrophages in situ are not possible but this process has been modeled in vitro (Alexander and Russell 1992; Rittig and Bogdan 2000; Handman and Bullen 2002). Two important caveats must be attached to the published reports to date: the types of macrophage used have been either a peritoneal exudate cell or a macrophage-like cell line (inappropriate host cells) and the parasites used have not been sandfly-derived metacyclic promastigotes but cultured forms that are sometimes not properly characterized. Nevertheless, these studies have shown that complement fixation by metacyclic promastigotes is not only an inevitable consequence of exposure to mammalian blood and tissue fluids but is an important adaptation for gaining entry to the host cell (Mosser and Brittingham 1997). Metacyclic promastigotes are relatively resistant to complement-mediated lysis and use the surface-bound complement components as ligands for binding to macrophage complement receptors. This promotes phagocytosis by the macrophage. After uptake and internalization in a phagosome, fusion with lysosomes occurs and the parasite inhabits a

secondary lysosome or phagolysosome (Antoine et al. 1998). During this process, the metacyclic promastigote transforms into an amastigote, a process that takes 12–24 h to complete. Interestingly, the parasite appears able to delay phagosome maturation until this transformation is complete (Swanson and Fernandez-Moreia 2002), a survival strategy mediated by LPG (Descoteaux and Turco 2002). Thereafter, the parasite remains in the amastigote form for the duration of the mammalian phase of the life cycle. Fully transformed amastigotes then continue to grow and divide within the phagolysosomal compartment of the host cell in a parasitophorous vacuole. Different species of parasite inhabit different sized vacuoles. The species causing Old World leishmaniasis all inhabit small vacuoles in which the vacuole membrane is closely opposed to the surface of the parasite itself. As the parasite divides so does the surrounding vacuole and, consequently, the host cell becomes occupied by multiple parasites and vacuoles. Amastigote division is by simple binary fission. Some of the New World parasites, for example *L. mexicana* (see New World leishmaniasis), occupy larger vacuoles, and these have a different effect on host cell endocytic traffic through their vacuoles (Antoine et al. 1998). After division, the parasites remain together in clusters within large vacuoles.

The phagolysosomal compartment presents two threats to amastigotes: the battery of lysosomal enzymes and low pH (4.5–5.5). Defense against the enzymes is mainly passive and relies on the unusual structures of the surface glycolipids and lipophosphoglycans rendering the amastigotes indigestible (Ilgoutz and McConville 2001). Low pH is not a problem as amastigotes are acidophiles: they have effective means of regulating their internal pH in an acidic environment; they are metabolically more active at low pH; and some species can only be cultured axenically in vitro as amastigotes at low pH (Bates 1993; Zilberstein and Shapira 1994). There is no known specific mechanism for escape from the host cell, although recent observations suggest the possibility that amastigotes are shed from peripheral vacuoles (Rittig and Bogdan 2000). The alternative is that parasites simply multiply until the host cell bursts open, making them available for uptake by other macrophages. Amastigotes are usually regarded as obligate intracellular parasites but this may not be strictly true: it is now possible to culture certain species axenically and at least in experimental infections it is possible to find extracellular amastigotes in heavily parasitized tissues. Despite this, the vast majority have an intracellular existence. Different *Leishmania* species infect macrophages at different sites in the body, but it is not known if amastigotes are specifically able to target subpopulations of mononuclear phagocytic cells or if they simply do not have access to or do not survive in macrophages in the wrong site. All amastigotes appear to be equivalent and there is no evidence for functionally distinct subpopulations.

TRANSMISSION FROM MAMMALIAN TO SANDFLY HOST

The opportunity for transmission from an infected mammalian host to a female sandfly occurs when the sandfly feeds. Sandflies are pool feeders, i.e. they possess cutting mouthparts that slice into the skin, and feed from the small pool of blood that seeps into the wound. Thus, despite their small size, 2–3 mm, sandflies give a noticeable and sometimes painful bite. Parasites causing cutaneous infections are acquired by a sandfly along with the bloodmeal if the fly happens to feed on a cutaneous lesion. Tissue damage from the bite releases infected macrophages or free amastigotes into the wound. Visceral parasites are probably acquired with the blood itself. Although the principal pathological events of visceral leishmaniasis occur in the spleen and liver, where the host cells probably remain resident, another site of infection is the bone marrow. This is a major site of hemopoiesis and blood monocytes infected with *Leishmania* amastigotes are released into the peripheral circulation and are thus available to feeding sandflies. It is also possible that infected monocytes leave the circulation and become resident in the skin to act as a source of parasites especially in the case of post kala-azar dermal leishmaniasis or the generalized leishmaniasis typical of canine infections with *L. infantum*. Nevertheless, in most endemic foci the acquisition of *Leishmania* parasites by individual flies is a rare event and the vast majority of flies are uninfected. The few infected flies are, however, efficient vectors.

BIOCHEMISTRY, MOLECULAR BIOLOGY, AND GENETICS

Surface membrane structure

The surface membrane proteins of *Leishmania* can be subdivided into two groups. Those in the first group are present at high copy numbers per cell and are major structural components of the surface membrane. Members of the second group are present at low copy numbers per cell and have been identified using functional assays, for example, enzymes, transporters, and ion pumps.

Three major surface components have been described: gp63 (or promastigote surface protease (PSP)), lipophosphoglycan and glycosylphosphatidylinositols (Ilgoutz and McConville 2001). gp63 is a major surface protein of c. 63 000 kDa found on the surface of cultured promastigotes in all species of *Leishmania* that have been examined (Chang et al. 1990; Etges and Bouvier 1991) and has also been demonstrated on the surface of sandfly-derived promastigotes. gp63 is a zinc metallopro-

tease, the active site of which is exposed on the external face of the surface membrane (an ectoenzyme). There is some evidence for low level expression of gp63 by amastigotes in some species, but efforts to demonstrate active protease on the amastigote surface have revealed very low or no activity. Potential functions of gp63 in the life cycle of *Leishmania* are not certain, but are likely to be most important in the sandfly or during the brief existence of metacyclic promastigotes in the mammalian host. In the sandfly, gp63 may fulfil a digestive function, helping to provide a supply of amino acids for the parasite. The most abundant substrate would be hemoglobin and by digesting this molecule gp63 could also help to provide pre-formed heme, an essential nutrient for *Leishmania*. It might also help the parasite to penetrate the peritrophic membrane, which is partially proteinaceous in nature. gp63 can also be released from the parasite surface, so it may be able to exert biological effects away from the surface of the parasite (McGwire et al. 2002).

After transmission to a mammalian host, the proteolytic activity of gp63 may help metacyclic promastigotes to defend themselves against lysosomal enzymes while they are transforming to amastigotes in the macrophage. gp63 has also been identified as a significant site of complement fixation on the promastigote surface (Mosser and Brittingham 1997) and has therefore been proposed to be involved in the binding of promastigotes to macrophages via complement receptors. Another potential role is in facilitation of parasite migration through host tissues (McGwire et al. 2003).

LPG is the major surface molecule found on the promastigotes of *Leishmania* species (Turco and Descoteaux 1992; Beverley and Turco 1998). LPG contains four covalently linked structural components: a phospholipid tail that anchors the molecule in the surface membrane; a glycan core of several saccharide residues that lies immediately above the surface membrane; a repeating phosphodisaccharide backbone comprising 15–30 phosphate-galactose-mannose units; and a cap of 2–3 saccharide residues. LPG has been most extensively studied in *L. major* but is assumed to fulfil similar functions in other species. The number of repeated phosphodisaccharide units varies between life cycle stages, approximately doubling in number between *L. major* multiplicative and metacyclic promastigotes. Modeling suggests that the backbone projects away from the surface; it also carries a number of short saccharide side chains which, in *L. major*, terminate mainly in galactose or arabinose residues. LPG is either absent or expressed at low levels on the surface of amastigotes.

LPG has been proposed to fulfil a variety of functions in both the sandfly and mammalian hosts. The unusual structure of LPG may give the parasites general protection against hydrolytic enzymes in both the sandfly midgut and macrophage phagolysosome. One specific function, that of mediating attachment of promastigotes to microvilli on the sandfly midgut epithelium, has been described above. Detachment from the midgut is correlated with developmental modification of the side chains of LPG in *L. major*. In procyclic promastigotes, the side chains terminate in galactose residues that can bind to the midgut epithelium. Subsequently, these are replaced with LPG-carrying side chains that terminate with arabinose residues. These do not bind to the microvilli, allowing the promastigotes to detach, migrate forward to the anterior midgut, and differentiate into metacyclic promastigotes (Pimenta et al. 1992). At the same time, the number of repeat units increases. This latter change is believed to be responsible for the observed resistance to complement-mediated lysis shown by metacyclic promastigotes, a prerequisite for survival in the mammalian host. LPG is the major site of complement fixation on the metacyclic promastigote. Mechanistically, it is proposed that elongated LPG interferes with complement lysis by steric hindrance, the components of a potential membrane attack complex being too far from and lacking access to the plasma membrane to enable insertion. LPG with bound complement components can be released from the surface, which may represent an additional defense mechanism.

LPG is also proposed to have functions in the establishment of the parasite in the macrophage (Descoteaux and Turco 1993, 2002). As with gp63, fixation of complement by LPG provides ligands that can be bound by macrophage complement receptors, stimulating phagocytic uptake of the metacyclic promastigote. LPG has a strong inhibitory effect on macrophage protein kinase C and, consequently, may have the effect of inhibiting signal transduction pathways that trigger microbicidal responses. It is also an efficient scavenger of toxic oxygen radicals.

Glycosylphosphatidylinositols (GPIs) have been found on the surface of both promastigote and amastigotes stages; in the latter, they are a major surface component (McConville and Ferguson 1993; Ferguson 1997). These glycolipids resemble the lipid anchor-glycan core moiety of LPG. The glycocalyx formed by these abundant molecules is assumed to help protect amastigotes against the potentially hostile environment of the phagolysosome.

Surface membrane biochemistry

In addition to gp63, a number of other ectoenzymes have been described on the surface membrane of promastigotes: acid phosphatase, 3′ and 5′ nucleotidases (Bates 1991). Promastigotes, and probably amastigotes, possess a surface membrane proton ATPase (Zilberstein and Shapira 1994) which serves an important function in pH regulation, extruding protons and preventing acid-

ification particularly in the phagolysosomal environment. Transporters for glucose, amino acids, ribose, nucleosides, and folate have also been described (Beck and Ullman 1991; Marr 1991; ter Kuile 1993; Zilberstein and Shapira 1994). The surface membrane has an unusual sterol composition with ergosterol as the major membrane sterol (Haughan and Goad 1991; Chance and Goad 1997). Two enzymatically active secretory molecules have been described in promastigotes; acid phosphatase (Bates and Dwyer 1987) and chitinase (Schlein et al. 1991). In addition, promastigotes and amastigotes secrete various phosphoglycans (Ilg et al. 1994; Ilg 2000).

Molecular biology

Leishmania spp., in common with other kinetoplastids, possesses several unusual features that differentiate them from other eukaryotes described to date, and thus merit brief mention here. The structure of kinetoplast DNA (kDNA) is unique for a mitochondrial genome (Shlomai 1994; Shapiro and Englund 1995; Lukes et al. 2002), but kDNA also exhibits a unique form of post-transcriptional RNA processing termed 'RNA editing' (Stuart and Panigrahi 2002). The 25–50 identical maxicircle DNA molecules of each kinetoplast encode various mitochondrial proteins but the primary RNA transcripts from these are not directly translatable. When compared to the final transcript, the gene sequences are found to contain insertions and deletions of uridine residues. The maxicircle primary transcripts are corrected in an editing process using short sequences, 'guide RNAs', which are themselves encoded by the other component of kDNA, the more numerous minicircles. This process is unique to kinetoplastids and is probably an ancient trait retained since the early divergence of the group from other eukaryotes.

Leishmania and kinetoplastids also exhibit several unusual features in the expression of their nuclear genes (Graham 1995; Stiles et al. 1999). Such genes are usually grouped together in polycistronic transcription units, an arrangement more commonly found in prokaryote organisms. Promoters have not been precisely defined, but there may be as few as one or two transcription start sites per chromosome (McDonagh et al. 2000; Myler and Stuart 2000). Once transcription is initiated, RNA polymerase then proceeds to transcribe in turn many individual genes of the array. Although transcription appears to be continuous, a giant transcript is not produced because, as it is synthesized, each gene is individually processed. A specific 39-nucleotide leader sequence is spliced in *trans* to the 5′ end and a poly(A) tail added to the 3′ end of each gene transcript. These two processes may be mechanistically linked. There are no intervening sequences in the coding regions of nuclear genes. Finally, gene expression itself is rarely, if at all, regulated at the transcriptional level in *Leishmania* (the general rule for eukaryotes) but occurs at a number of post-transcriptional steps depending on the specific gene concerned. These include the RNA processing steps mentioned above, mRNA stability, translational control and post-translational turnover of proteins.

Genetics

Leishmania appear to be essentially diploid organisms (Bastien et al. 1992; Lighthall and Giannini 1992) although occasional examples of aneuploidy have been found. Diploidy has been confirmed for a number of specific genes in which two rounds of gene disruption are required in order to generate null mutants. Chromosomes do not condense during mitosis but can be separated and enumerated by pulsed-field gel electrophoresis. The use of this technique, the identification of genetic markers for specific chromosomes and an ongoing effort to sequence the *Leishmania major* genome have recently established the karyotype of *Leishmania* (Ivens and Blackwell 1999). There are 36 chromosomes in most species, ranging in size from 285 to 2 800 kb. Species related to *L. mexicana* and *L. braziliensis* (both from the New World) possess 35 and 34 chromosomes respectively, a result of possessing fused versions of certain chromosomes that are separate in other species (Britto et al. 1998). However, synteny is well conserved between species examined to date, variation residing mainly in the spacing of genes rather than their order (Britto et al. 1998; Ravel et al. 1999). There is some circumstantial evidence for a sexual cycle in *Leishmania* (Bastien et al. 1992), but so far no one has succeeding in performing a genetic cross (as in African trypanosomes). Population genetic data indicate that *Leishmania* has a predominantly clonal structure and reproduces asexually (Tibayrenc et al. 1990; Victoir and Dujardin 2002). Therefore, sexual reproduction, if present, may be more important on an evolutionary scale than in the routine life cycle progression of the parasite.

CLINICAL ASPECTS

Clinical manifestations

One of the most remarkable features of the leishmaniases is the diversity of diseases caused by morphologically similar parasites living in a single series of cells (Figure 11). This diversity is by no means fully explained by genetic diversity among the parasites and is generated in part by the variety of host responses to the infection and in part by the (largely unexplained) restriction of the parasites to specific parts or organs of the body. One factor restricting parasites to the skin may simply be temperature, to which some species of

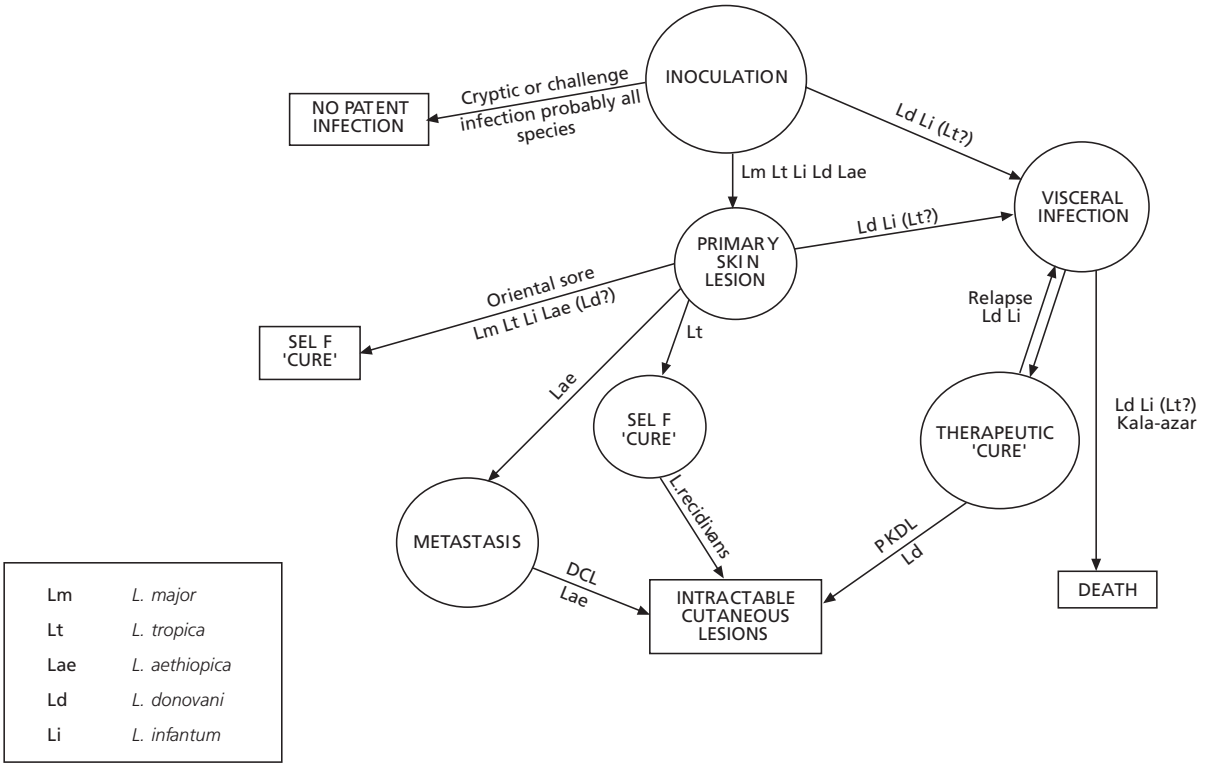

Figure 11 *The 'leishmaniasis spectrum', showing the potential progress and outcome of infection with Old World species. (Modified from Molyneux and Ashford 1983)*

Leishmania are particularly sensitive. In experimental animals, the genetic make-up of the host has been shown to have a great effect on the host response to infection.

There is considerable evidence that even the most virulent *Leishmania* parasites may cause no detectable disease in certain individuals. Wherever transmission occurs, there are numerous people who have positive immunological reactions but no cutaneous scar or history of visceral disease. Sub-clinical infection must be particularly common in foci of *L. infantum*. Here, disease in adults is usually associated with underlying immunosuppressive disease and may then be very common; even among children overt disease may be extremely rare despite intense transmission.

CUTANEOUS LEISHMANIASIS OR ORIENTAL SORE

A single cutaneous lesion, or leishmanioma, at the site of each infective sandfly bite is characteristic of infection with *L. tropica*, *L. major*, *L. aethiopica*, certain strains of *L. infantum* and, rarely, *L. donovani*. Oriental sore, caused by *L. major* or *L. tropica*, is usually painless and self-curing, and is frequently passed off as a trivial matter. Although this may be true of a single lesion in a hidden place, multiple lesions of *L. major* or disfiguring facial lesions due to *L. tropica* may be physically or psychologically crippling.

Generally, all lesions on any one patient have a similar appearance and progress synchronously. In *L. major* infection, the center of the 'wet' lesion becomes necrotic and exudative forming a loose crust of congealed serum above a granulomatous base that eventually produces the characteristic scar. *L. major* lesions may number more than 100. With *L. tropica* the 'dry' lesion is more swollen and less necrotic; the exudate is less profuse and accumulates as a thicker crust. Numerous lesions are rare, the average number being around two. These differences are by no means consistent and are certainly not diagnostic. *L. aethiopica* lesions are even more swollen and less necrotic than those of *L. tropica*; frequently they are barely exudative, with gradual scaling or exfoliation of the dermis at the center. These lesions often last for years before healing. Cutaneous lesions resulting from *L. infantum* resemble those of *L. tropica* but are generally smaller and more indolent.

Oriental sore is not usually associated with systemic manifestations, although there may be enlargement of the draining lymph nodes. The necrotic centers of lesions are heavily contaminated with bacteria but these are not usually invasive, so inflammation, suppuration, and pain are atypical.

LEISHMANIASIS RECIDIVANS

Leishmaniasis recidivans (LR) is an unusual sequel of oriental sore caused by *L. tropica* infection. In this condition, small and usually non-ulcerating lesions appear, mainly on the margin of an apparently healed scar of oriental sore. These may last indefinitely, gradually extending the limits of the initial scar, and causing severe disfigurement. LR is associated with a strong cell-mediated immune response; as it closely resembles cutaneous tuberculosis, both superficially and histologically, the name 'lupoid leishmaniasis' is sometimes used.

DIFFUSE CUTANEOUS LEISHMANIASIS

Diffuse (more correctly 'disseminated') cutaneous leishmaniasis (DCL) is a rare form of disease, caused by *L. aethiopica* in the Old World; just over 100 cases have been recorded. The parasites are restricted to the skin but become widely distributed over much of the surface in large, swollen plaques and nodules. DCL resembles lepromatous leprosy, for which it was initially mistaken, but the abundant parasites in the nodules provide easy distinction. This is an immunologically anergic condition in which neither humoral nor cell-mediated responses are activated; it is very difficult to treat and may last for the rest of the greatly disrupted life of the patient.

VISCERAL LEISHMANIASIS OR KALA-AZAR

Visceral leishmaniasis is characteristic of infection with *L. donovani* and *L. infantum*. There are also suggestions that occasional cases are caused by *L. tropica*. The two main viscerotropic species cause broadly similar diseases although *L. infantum* mainly affects young children and has a greater tendency to cause lymph node enlargement. The general course of the disease is thought to be closely related to the health status of the patient at the time of infection and longitudinal studies have provided good evidence that malnutrition exacerbates *L. infantum* infection (Badaro et al. 1986).

The infection begins at the site of the infective sandfly bite, where there may be an initial ulcerating lesion. This has been best described in dogs, where its occurrence does not reflect the eventual outcome (Vidor et al. 1991). In humans, a leishmanioma is rarely seen and, if present, it may become a self-limiting lesion resembling oriental sore without producing visceral disease.

The clinical features of visceral leishmaniasis are well described by Rees and Kager (1987). Typically, visceral disease develops after an incubation period of 2–6 months and is accompanied by a persistent, irregular, low-grade fever, but onset may be delayed for many years. Once established, subsequent development of disease is quite variable; onset of severe symptoms may be very acute with rapid progression to life-threatening disease within 2 weeks, or progression may be insidious, almost unnoticed, and probably passed off by the patient as malaria, until the abdominal swelling becomes a major concern. Splenomegaly is the most consistent and noticeable sign. The spleen becomes enormously enlarged, extending well below the umbilicus, its size emphasized by an accompanying cachexia. Hepatomegaly is less consistent and less extreme but is usually present in late cases. The hematological picture is greatly altered with anemia and leukopenia being the most manifest changes. The outcome of untreated fully symptomatic visceral leishmaniasis is usually fatal.

POST KALA-AZAR DERMAL LEISHMANIASIS

Post kala-azar dermal leishmaniasis (PKDL) is a relatively common consequence of therapeutic cure from visceral leishmaniasis caused by *L. donovani*. It is not associated with *L. infantum* infection. PKDL is occasionally seen in patients with no history of visceral disease but only in places where *L. donovani* is transmitted; this is probably a sequel to subclinical infection. Sometimes, PKDL develops before the visceral infection has cured but its onset may be delayed for as much as 2 years. The extent to which chemotherapy actually causes PKDL is an interesting conundrum and one that is unlikely to be resolved soon as visceral disease is always treated if drugs are available and untreated cases have a poor prognosis. PKDL has been reported in some 20 percent of cured cases in India and is said to be rare in Africa but a very high incidence has been recorded in a recent Sudanese epidemic (Zijlstra et al. 1994).

PKDL is a variable disease; it may start as a widespread punctate, progressive depigmentation giving the skin a mottled or freckled effect, or may first be noticed as discrete papules, mainly on surfaces exposed to light. It can progress to produce an extensive surface of coalescing papules or large discrete nodules which superficially resemble DCL or lepromatous leprosy. The lesions are delicate, but do not ulcerate unless traumatized. The duration of the untreated condition, the numbers of parasites and the immune responses of patients with PKDL are very variable.

LEISHMANIA AND HUMAN IMMUNODEFICIENCY VIRUS (HIV) COINFECTION

Most of the information on coinfection relates to *L. infantum* acquired in south-western Europe (France, Italy, Portugal, and Spain); few coinfections with other *Leishmania* species have been described to date although they must certainly occur. From 1990–98, 50 percent of visceral leishmaniasis cases presenting in these countries were coinfected with HIV (Dereure et al. 1995; WHO 2000). Visceral leishmaniasis and HIV together are synergistic infections because visceral

leishmaniasis accelerates the development of aquired immune defeciency syndrome (AIDS) and the presence of HIV infection enhances the spread of visceral disease (Wolday et al. 1999). The diversity of strains found is much greater than usual and strains that are normally associated with cutaneous disease may become visceral in coinfection (Pratlong et al. 1995). Serological evidence suggests that HIV may both activate subclinical leishmaniasis and make the patient susceptible to a new infection (Gradoni et al. 1993); serology is of little use in diagnosing coinfection. In a group of patients in Spain, the clinical presentation was characteristic of kala-azar and most were at CDC HIV stage 4 with fewer than 200×10^6 CD4+ lymphocytes per l. Visceral leishmaniasis was the first reported severe infection in 10 of 47 cases (Medrano et al. 1992). Other workers have found a wider diversity of presentations, frequently with infection of the upper alimentary tract (Peters et al. 1990). Many authors have suggested that visceral leishmaniasis should be included in the list of opportunistic infections indicative of AIDS (e.g. Altes et al. 1991). The predominance of intravenous drug users among these patients suggests that syringe transmission may occur (Alvar and Jimenez 1994). Cases of coinfection in Europe are expected to fall as a result of availability of new anti-HIV drugs but the problem is increasing in eastern Africa, the Indian subcontinent, and South America. The true extent is unclear, but it is certainly grossly under-reported, as few of these countries implement active surveillance of *Leishmania*/HIV coinfection.

IMMUNOLOGY

Introduction

The responses of the immune system to *Leishmania* infection are highly complex (reviewed by Mauel and Behin 1987; Liew and O'Donnell 1993; Bogdan and Rollinghoff 1999). They may accelerate cure or exacerbate the disease depending on the particular circumstances. This is partly due to the effects of genetic variation in the mammalian host, partly due to genetic variation in the parasites between species and strains and partly due to chance factors, such as the location, inoculum size, and number of infective bites received.

Host genetic variability

The evidence that genetic variation in humans contributes to variability in their immune responses and clinical outcome is mainly anecdotal and essentially based on the wide clinical spectrum produced by apparently identical parasites. More definitive evidence is now accumulating (see Blackwell 1999), but even under circumstances in which individuals share the same environment and differences exist in incidence or severity of disease, it is impossible to be certain whether this reflects human genetic variation or, for example, different numbers of bites received. The main evidence supporting the importance of genetic variation comes from experimental studies conducted with inbred strains of mice (reviewed by Bradley 1987; Blackwell 1992). It is difficult to determine the extent to which these findings can be extrapolated to human patients. Nevertheless, this experimental approach has proved productive and several genetic loci have been identified in the mouse that are linked to resistance phenotypes. The genes encoding some of these have now been cloned and, although the functions of these are not fully resolved, this opens up the possibility of a search for homologs in the human genome. This should lead to progress in assessing the contribution of human genetic variability to the clinical spectrum of disease.

Human cutaneous leishmaniasis

Spontaneous cure of uncomplicated *L. major* and *L. tropica* infection usually results in a solid immunity. There is a marked development of cell-mediated reactions but a weak antibody response, although specific antibody can be detected. The cell-mediated reactions are responsible for a marked delayed type hypersensitivity (DTH) response to the inoculation of leishmanin (washed promastigotes in 0.5 percent phenol saline) in active and cured cases. The DTH response can often be detected before healing. In persistent *L. tropica* infections that result in LR there is still a strong DTH response, indicating that the parasite can survive despite the high immunological reactivity of the host. In contrast, DCL caused by *L. aethiopica* is characterized by a lack of DTH response but the presence of antibodies thus tending more to resemble response to visceral leishmaniasis.

Human visceral leishmaniasis

Radical cure of *L. donovani* infection by chemotherapy can also generate protective immunity in some individuals. In contrast to cutaneous leishmaniasis, cell-mediated immunity is impaired in active kala-azar patients who consequently lack a DTH response but this can be demonstrated after cure. There is, however, a marked humoral response to visceral leishmaniasis. Polyclonal B cell activation produces mainly immunoglobulin (Ig)G and IgM antibody, most of which is non-specific, but high titers of specific antibody can also be detected. In PKDL, a curious situation arises in which there seems to be immunity in the viscera but not in the skin. Only a proportion of PKDL patients show a DTH response; antibody levels are elevated but are not as high as in active kala-azar.

Experimental leishmaniasis

The relative paucity of information on the immunology of human leishmaniasis is in contrast to an explosion in the literature relating to experimental infections in inbred strains of mice particularly using *L. major* (Liew and O'Donnell 1993; Milon et al.1995; Solbach and Laskay 1995, 2000; Nabors 1997; Alexander et al. 1999; Sacks and Noben-Trauth 2002). This explosion is due not only to the potential impact that such work may eventually have on human medicine, but also to the role that *Leishmania* has played in fundamental immunological research itself. The relatively recent nature of these findings, together with the difficulties of investigating human immunology, means that the extent to which they can be extrapolated to human leishmaniasis is difficult to predict. In all of these experimental studies, it should be remembered that the infection occurs against a specific genetic background, usually in a highly susceptible strain of mouse, and that the interaction between innate genetic factors and specific immune responses is not well understood. Despite these caveats, some of the major findings are likely to be borne out and thus merit brief discussion. The main effector cells in murine cutaneous leishmaniasis are two subsets of CD4+ T cells, T helper 1 (Th1) and T helper 2 (Th2) cells, each associated with a distinct cytokine profile. Resistance and healing in mice is associated with a Th1 type response whereas susceptibility and disease progression is accompanied by a Th2 response. These polarized Th1 or Th2 responses have not been demonstrated in murine *L. donovani* infections which instead are associated with an absence of a Th1 response in susceptible strains (Kaye 1995). Early events in the dermis and epidermis of the skin may play a crucial role influencing the development of resistance or susceptibility (Moll 1993; Solbach and Laskay 1995; Ritter and Korner 2002). A Th1/Th2-like dichotomy in CD4+ T cell clones can be demonstrated in human leishmaniasis (Kemp et al. 1993, 1994; Ghosh et al. 1995). The main effector cell in protective immunity is the macrophage host cell itself, in which the killing mechanism is a cytokine-induced production of nitric oxide (Liew and Cox 1991).

PATHOLOGY

In visceral leishmaniasis, parasites may be found in practically every organ, whereas they are largely limited to the skin in cutaneous leishmaniasis; nevertheless the histological spectrum of the different diseases is surprisingly uniform. Cells of the mononuclear phagocyte system are infected (Ridley 1987), particularly the more actively phagocytic members of the series. Further phagocytic cells are attracted to the site which, in turn, become infected so a colony of infected cells is produced. The parasites may be restricted to the initial cutaneous site or may, after a variable delay, disseminate in the blood rather than the lymphatics to establish metastatic colonies in almost any organ. The temperature dependence of each species may partly be responsible for the ultimate distribution of the lesions. Dissemination is also limited by the histological immune response.

In cutaneous leishmaniasis, a spectrum of histological response to infection, somewhat analogous to that in leprosy, is based on the amount of lymphocyte, plasma cell, and giant cell infiltration constituting the granulomatous inflammation. The minimal, anergic, (Ridley's 'group I') response is best seen in DCL with abundant heavily infected macrophages, few other cells and no giant cells. There is little necrosis and no ulceration. The other extreme, the 'group V' hypersensitive response, is tuberculoid, with an epithelioid cell granuloma, large Langerhans cells, variable plasma cell numbers and scanty lymphocytes. Few parasites are present and, again, there is no necrosis. Langerhans cells may migrate to the draining lymph nodes where they present antigen to T cells initiating the immune response (Moll 1993). Between these two histologically stable extremes, both of which produce long lasting lesions intractable to treatment, are three less well defined categories which, to some extent, represent a progression associated with lymphocyte infiltration, variable amounts of necrosis, and healing. Necrosis is the main feature of an effective immune response and subsequent healing, whereas small numbers of parasites may be destroyed by macrophages and giant cells.

The histological pattern in deep tissues is less fully described but seems to be similar; again, the main feature of healing is the presence of lymphocytic granulomata and necrotic centers. In contrast to cutaneous leishmaniasis, however, natural healing is not the rule and the lesions are more like the anergic, group I type described above with widely disseminated proliferations of infected macrophages and little infiltration. Most of the pathology is caused by this hyperplasia and damage to the organs caused by associated congestion. According to El Hag and Hashim (1994), the liver shows infected Kupffer cells and macrophages together with chronic mononuclear cell infiltration of the portal tracts and lobules, ballooning degeneration of the hepatocytes and fibrosis of the terminal hepatic venules.

DIAGNOSIS

Relative unfamiliarity with the leishmaniases among practitioners in non-endemic areas occasionally leads to serious misdiagnosis and mistreatment. A good travel history may arouse suspicion in those versed in geographical medicine, but reference to a tropical specialist is usually required to confirm the diagnosis. In areas where the disease is better known, clinical diagnosis is frequently regarded as sufficient. Although this may be

justified during epidemics, a number of alternative diagnoses will inevitably be missed if demonstration of the parasites is not attempted on all patients.

Clinical diagnosis

Clinical diagnosis of any of the leishmaniases depends primarily on awareness. None of the signs or symptoms is diagnostic but, when combined with a relevant travel history, or in an endemic area, a good presumptive diagnosis may be made clinically and can be confirmed parasitologically. 'Diagnosis' by therapeutic trial is commonly practiced but is unsatisfactory, particularly in view of the expense and potential toxicity of the drugs.

Visceral leishmaniasis is often mistakenly recorded post-mortem as 'malaria that failed to respond to treatment' (and is probably included in malaria mortality statistics). The typical patient presents at a late stage, with persistent but fluctuating low grade fever, weight loss giving the appearance of severe starvation, and spleno- or hepatosplenomegaly. The patient is usually alert and feels remarkably well, considering his or her condition. The skin is sometimes said to be 'muddy', 'pale' or 'dark', but these are not diagnostically useful descriptions. There is frequently persistent diarrhea. Lymphadenopathy is an irregular feature.

Non-specific laboratory tests will show marked leukopenia (pancytopenia, mainly neutropenia), anemia, raised serum proteins with reversal of the albumin/globulin ratio due to greatly raised IgG levels.

Manson-Bahr (1987) suggests the following differential diagnoses: malaria, relapsing fever, trypanosomiasis, brucellosis, liver abscess, tuberculosis, tropical splenomegaly, myeloid leukemia, lymphoma, cirrhosis of the liver, schistosomiasis, thalassemia, histoplasmosis, and various gammopathies.

Diagnosis of visceral leishmaniasis in the presence of HIV infection is particularly difficult as the presentation may be very atypical and serological tests may be negative.

All forms of cutaneous leishmaniasis usually present without systemic disease. Typical lesions of oriental sore are readily recognized by the raised edges, necrotic, exudative center with granulomatous base, long duration, and painlessness. Less typical lesions take a bewildering array of forms and must be distinguished from basal cell carcinoma, tuberculosis, various mycoses, cheloid and lepromatous leprosy.

LR may be indicated by the presence of a scar and positive skin test, whereas DCL shows no ulceration or scarring and has a negative skin test.

Parasitological diagnosis

A diagnosis of leishmaniasis can be formally confirmed only by the demonstration of the parasites. These are readily seen in smears or touch preparations of infected tissue stained with Giemsa's stain, preferably at pH 7.2 rather than the pH 6.8 normally used in hematology. Sections of tissue stained more conventionally with hematoxylin and eosin are much more difficult to interpret so the diagnosis must be suspected before material is prepared. Preparations from cutaneous lesions may be made from punch biopsies, but it is usually sufficient to take a small quantity of material from the living, but diseased, tissue at the edge of the lesion by a slit smear or other minimally invasive technique.

Deeper tissues may be sampled by needle biopsy. Material may be aspirated from lymph nodes following injection of a small quantity of physiological saline. Bone marrow smears are made using standard hematological techniques. Spleen aspirate is the most reliable material for demonstrating parasites in kala-azar. Although many physicians are reluctant to take spleen aspirates others have no hesitation and even use this method to monitor treatment. It is vital to use the correct technique and equipment with confidence so that the capsule of the spleen is penetrated by a fine needle for only a fraction of a second (see Bryceson 1987a for precise instructions).

Parasites may be scanty and are mostly extracellular in slide preparations so these may have to be examined for at least 15 minutes using a $\times 100$ oil immersion objective before the diagnosis can be confirmed. Amastigotes are identified by their size (3–5 μm) and the possession of a nucleus and kinetoplast; although smaller, the kinetoplast is often easier to detect because the DNA is very densely packed and produces a deep purple spot or rod on staining. It may be possible to provisionally identify the parasites to species level by considering the circumstances and clinical features. *L. major* and *L. tropica* can be separated with some confidence by the abundance of parasites in the latter, their smaller size and the presence of more numerous parasites in each infected cell. Complete identification requires the isolation of parasites in culture.

Whatever material is collected, it is desirable to culture the parasites in blood-agar or insect tissue culture medium so that they can be identified at strain level by isoenzyme analysis. For special purposes, material can be inoculated into a hamster, generally the most susceptible experimental host. Monoclonal antibody and DNA probes, with or without PCR amplification, have been developed for identification of the parasites. These are not yet commercially available but are of great use in epidemiological or ecological investigations.

Two indirect approaches for investigating the presence of parasites in clinical samples are currently under development. There are numerous publications describing the potential application of PCR to *Leishmania* diagnosis (for example, Wiegle et al., 2002; Salotra et al. 2001; Lachaud et al. 2001). There is, as yet,

no general consensus about which sequences are the best targets for diagnosis, but repetitive nuclear genes, such as ribosomal and mini-exon genes, or kDNA are often used. Also, there is no one-step PCR diagnostic test that will identify all species. However, these drawbacks are likely to be solved in the near future. The second area of advance is in antigen detection systems, specifically the detection of antigen in the urine of patients with visceral leishmaniasis (Attar et al. 2001; Sarkari et al. 2002). This is particularly welcome as this is a completely non-invasive technique, a significant advantage compared to bone marrow or spleen biopsy. As yet, these methods have not supplanted direct parasitological diagnosis and require further testing and clinical trials but, given their technical advantages, this seems a matter of time.

Immunological diagnosis

Immunological diagnosis (reviewed by Kar 1995) is of value in screening suspected kala-azar patients, other than those coinfected with HIV, and in epidemiological studies.

In the formol-gel test, a drop of full strength formalin is added to 1 ml of serum. A positive result is indicated by the rapid and complete coagulation of the serum. This simple test merely indicates greatly increased serum proteins and thus is non-specific. Nevertheless, it is still widely used; in order to be acceptable in peripheral clinics in endemic areas, this is the level of technology that any new test will have to approach.

More specific tests, which become positive earlier in kala-azar, include the indirect fluorescent antibody test (IFAT), the enzyme-linked immunosorbent assay (ELISA) and a direct agglutination test (DAT). This last technique requires minimal equipment, is robust in the most difficult conditions and is exquisitely sensitive. DAT is fast becoming available for use at peripheral-level clinics and the development of freeze-dried antigen (Meredith et al. 1995) promises even wider availability of this test. For active case detection, numerous positive responses to serological tests are found in people who show no disease. To treat all these people as patients would be a mistake; probably the best thing is to examine them carefully, treat those with signs of disease and to monitor the others carefully.

The specific reagents for the above serological tests are not readily available commercially, but they can be prepared relatively easily in the laboratory.

A delayed hypersensitivity reaction to intradermal crude *Leishmania* antigen is produced in healing or cured cases of both cutaneous and visceral leishmaniasis. This leishmanin, or Montenegro skin test is of great value in epidemiological studies, but is of little clinical use as the number of positive reactors is usually much greater than the number with a history of disease suggesting that either the test is non-specific or there is a considerable amount of sub-clinical infection.

EPIDEMIOLOGY

Introduction

Knowledge of the epidemiology of the leishmaniases has benefited in recent years from our growing understanding of the taxonomy of the group and from the possibility of accurate identification of morphologically similar parasites derived from human cases, sandfly vectors or non-human mammalian hosts. Current taxonomy corresponds much better with ecology and epidemiology than it does with clinical manifestations (see Molyneux and Ashford 1983). Anomalies and questions remain and the 'spectral epidemiology' (different diseases caused by ostensibly similar organisms) is largely unexplained.

It has been conservatively estimated that, in the Old World, 150 million people in 40 countries are at risk of cutaneous leishmaniasis and 180 million people in 39 countries are at risk of visceral leishmaniasis. The total number of reported cases has been estimated at 240 000 and 73 000 annually for cutaneous and visceral leishmaniasis respectively but this is doubtless a gross underestimate of the real numbers (Desjeux 1991; Ashford et al. 1992a). The figure of 12 million cases annually (sometimes misquoted as 1.2 million) was estimated some time ago by Walsh and Warren (1979), but although the World Health Organization (WHO 1990) uses the higher figure of 12 million, it is hard to know how it was derived.

Although transmission is possible by contagion, by transfusion or in utero, these routes have little if any known epidemiological significance. Effectively, all transmission is by the bite of a phlebotomine sandfly (Diptera: Phlebotominae) (reviewed by Killick-Kendrick 1990b). The leishmaniases illustrate the entire gamut of zoonotic patterns of transmission.

Epidemiology of *L. major* infection

L. major is widely distributed in the Palaearctic and Aethiopian zoogeographical regions along the northern and southern fringes of the Sahara, extending south into northern Kenya and through Arabia, southern Iraq and Iran, into the central Asian states of Turkmenistan, Uzbekistan, and northern Afghanistan. It also ranges through Iranian and Pakistani Baluchistan to the Indian border in Rajasthan (see Figure 1).

Throughout this wide range, the parasite is restricted to arid and semi-arid zones. Its broad distribution seems to be determined by that of its vectors and its detailed distribution is largely determined by that of its natural mammalian hosts.

The three known vectors belong to the subgenus *Phlebotomus* (*Phlebotomus*) of which *P. papatasi* is the most widespread and abundant. *P. papatasi* transmits *L. major* in all but the sub-Saharan and Indian parts of its distribution; it is replaced by *P. duboscqi* in the former and *P. salehi* in the latter. *P. papatasi* has a much wider distribution than *L. major*, especially in northern India, but here it is largely synanthropic and has no access to suitable reservoir hosts. The efficiency of this species as a vector may be affected by the plant juices on which it feeds, some of which may inhibit growth of the parasites (Schlein and Jacobson 1994b).

The known reservoir hosts of *L. major* are rodents. In the central Asian deserts, the great gerbil *Rhombomys opimus* lives in dense colonies with deep and complex burrow systems that provide shelter and possibly a breeding site for *P. papatasi*. The gerbils breed throughout the warmer months and by the end of the transmission season, in autumn when the rodent population is greatest, almost every animal may be infected. The infection is usually restricted to the ears, which become only slightly swollen and eroded, and there is no indication that the rodent is seriously affected.

Great gerbil colonies are best developed in areas where the soil is deep and of a consistency that allows permanent burrows to be constructed. These conditions are found on the alluvial fans in the valleys of the largest rivers draining the great central Asian loess deposits, such as the Amudarya.

The distribution of the rodent extends much further north in central Asia than that of the vector. In these zones, they are infected with other parasites, *L. gerbilli* and *L. turanica*, which behave similarly in the rodent but do not infect humans and are transmitted by different sandfly vectors (Strelkova et al. 1993).

The other rodent reservoir host of *L. major*, which has very narrow habitat requirements, is the fat sand rat *Psammomys obesus*. This host maintains populations of the parasite in Algeria, Tunisia, Libya, north Sinai, the Jordan Valley, southern Syria, and much of Arabia. This rodent is unique in being able to derive its entire nutrient and water requirements from the succulent, but highly saline, stems and leaves of halophilic plants of the family Chenopodiaceae. These plants dominate the internally draining salt pans, sebchet or playas of much of the desert fringes and it is here that the sand rats are concentrated. *P. obesus* burrows are less deep or extensive than those of *R. opimus* and provide a less favorable habitat for *P. papatasi*. Furthermore, the rodents breed mainly in the winter when there is no transmission so the young are not exposed to infection until they are a few months old. Nevertheless, all the evidence supports the conclusion that *P. obesus* is responsible for the maintenance of *L. major* in most of this part of its range.

Some foci of *L. major* in the Palaearctic occur in the absence of both *P. obesus* and *R. opimus* and have been attributed to various rodent hosts such as jirds, *Meriones* spp. (Rioux et al. 1982) or the mole rat *Nesokia indica*. The structure of these foci, notably that on the Iraq–Iran border, remain to be fully understood.

In its Aethiopian range, where *L. major* is usually transmitted by *P. duboscqi*, various rodents have been found infected, notably the grass rats *Arvicanthis* spp. and the multimammate rats *Mastomys* spp., in which the parasites are found in the viscera but do not seem to cause serious pathology. These rodent populations fluctuate wildly and do not have narrow habitat requirements so they are not good candidates for the maintenance of vector-borne infections. Possibly there is no individual rodent species maintaining the parasite but a diversity of hosts may be required.

L. major infection in humans is most conspicuous in epidemics in groups of people entering sparsely inhabited zoonotic foci. Major outbreaks have occurred in military groups and in workers on development projects. Development frequently alters the environment sufficiently so that, following a brief epidemic period, the infection disappears as has been seen particularly in irrigation schemes. Residents in zoonotic foci usually become infected at an early age and, being familiar with the infection, are less concerned.

The dynamics of human infection are largely governed by the rate of exposure to infection and the almost complete resistance to reinfection. Beljaev and Lysenko (1977) have modeled the stable-state system, making minimal, realistic assumptions; they show that at low rates of exposure (fewer than 0.05 exposures per person per year) incidence is proportional to this rate. They term locations where these conditions prevail 'hypoendemic foci'. In contrast, hyperendemic foci are those where the exposure rate is greater than 0.25 exposures per person per year. In such foci, lifetime incidence is largely independent of the exposure rate, change in which alters only the mean age at which people become infected. As most people who live in such hyperendemic foci are infected when young and subsequently become immune, the incidence is dependent on the rate at which non-immune people are recruited into the population, whether by birth or immigration.

In sub-Saharan Africa, outbreaks are much less frequent and human cases occur sporadically in both space and time. In some foci, in Ethiopia and Kenya for example, human infection is extremely rare even in places where infected rodents have been found.

Transmission between humans without a mammalian reservoir host has not been well established, although the possibility cannot be excluded. A series of epidemics in Khartoum and nearby towns in Sudan in the late 1980s occurred in dense, stable human populations that had never previously known the infection (El Safi et al. 1988). The best available explanation is that the parasite was introduced by displaced people from endemic areas to the west and that it was trans-

mitted to residents by the abundant *P. papatasi* living close to the Nile.

Epidemiology of *L. tropica* infection

L. tropica is mainly found in the ancient cities of west and central Asia (see Figure 1). Generally, *L. tropica* inhabits slightly wetter areas than *L. major*. The two species are geographically sympatric in places but are ecologically separated. Vernacular names for the infection frequently refer to endemic cities, for example Balkh sore, Baghdad boil, Aleppo evil, and Delhi boil; this probably reflects the perception of visitors rather than indigenous people.

Urban cutaneous leishmaniasis is transmitted by *Phlebotomus* (*Paraphlebotomus*) *sergenti* throughout its range. This sandfly can reach high populations in crowded cities and suburbs but is not restricted to the peridomestic environment. Dogs have been found to be infected but it is generally thought that the main hosts are humans. Unlike *L. major*, the rate of exposure to infection depends on the number of active human lesions as well as other factors. The human lesion normally lasts around 1 year and people with cured lesions are immune. Therefore, in conditions of potentially high transmission, most people are immune, but few are susceptible leaving even fewer actually infected. The maintenance of stable transmission in a stable human population has been estimated to require some 20 000 sandfly bites per person per year which, in the seasonal climates of central Asia, may mean 100 bites per person per night. Such conditions are rarely, if ever, met and the infection must rely either on movements of people (Ashford et al. 1992b) or on spatial heterogeneity in the immunity of the population, moving from place to place in localized epidemics (Ashford et al. 1993). In this way *L. tropica* resembles a viral infection such as measles rather than most other eukaryotic parasites.

There are reports of *L. tropica* infection occurring sporadically in rural settings, which cannot easily be explained by the above patterns. Furthermore, the finding of *L. tropica* causing visceral leishmaniasis in American soldiers who served in the Gulf region during the first Gulf war in 1991 (Magill et al. 1993, 1994) and in Kenyan and Indian villagers (Mehbratu et al. 1989; Sacks et al. 1995) in the heart of areas of *L. donovani* transmission, pose intriguing epidemiological questions for which no sensible answer can yet be proposed.

It was thought at one time that *L. tropica* did not occur in Africa. Parasites from an ostensibly zoonotic outbreak of cutaneous leishmaniasis in Tunisia were identified as a new species, *L. killicki*, which, on the cladograms of Rioux et al. (1990) (see Figure 3), is close to *L. tropica*. A wide variety of *L. tropica*-like strains are responsible for another apparently zoonotic focus in Morocco (Pratlong et al. 1991). Parasites from sporadic cutaneous cases, hyraxes *Procavia* spp. and from the sandflies *P. rossi* and *P. guggisbergi*, in Namibia and Kenya were found to be intermediate between the original *L. killicki* and *L. tropica*. It is a matter of opinion whether these parasites should be included with *L. tropica* or not (Sang et al. 1992). Occasional aberrant cutaneous, visceral, or mixed infections have been reported elsewhere in Africa, notably in Tanzania, Zambia, and Malawi (Pharoah et al. 1993). These parasites have not been isolated and their identity is unknown but presumably they originated in zoonotic foci that await discovery and description.

Epidemiology of *L. aethiopica* infection

L. aethiopica is restricted to the highlands of East Africa in Ethiopia and Kenya, between c. 1 800 m and 2 700 m above sea level and within the 800 mm isohyet (see Figure 1). In all known foci, it is associated with hyraxes (Hyracoidea) which are the natural reservoir hosts (Ashford et al. 1973). These animals have very poor temperature regulation and live in deep clefts in rocks or trees in which they can find the shelter they require for the maintenance of their body temperature. Despite this restriction, they are found at all altitudes from below sea level in the Danakil desert to above 4 000 m where there is frost every night. Hyraxes are long-lived and live in colonies or family groups so, although their rate of reproduction is low, they are good candidate reservoir hosts. Parasites have been isolated from normal skin and external mucosa showing no sign of the infection which presumably lasts a long time.

The vectors, *P. longipes* and *P. pedifer*, have less specific habitat requirements, being common in houses or associated with cattle, but they are restricted in altitude. The distribution of the parasite is, therefore, governed by the habitat of the reservoir host and the altitude range of the vectors. Wherever they have been adequately studied, human cases can be attributed to the nearby presence of infected hyraxes. Incidence of disease in humans is rarely high and the rare cases of diffuse cutaneous leishmaniasis caused by this parasite have not been explained epidemiologically.

Epidemiology of *L. donovani* infection

L. donovani is surely one of the great scourges of mankind having been responsible for a series of historical deadly epidemics each causing depopulation of affected areas. The geographical distribution of *L. donovani* infection is somewhat labile (see Figure 2). In the Indian subcontinent, it occurs in the valleys of the Ganges and Brahmaputra Rivers, in Bihar, lowland Nepal, West Bengal, Bangladesh, and Assam, as well as further south, around Madras (reviewed by Sanyal

1985). It is often presumed that visceral leishmaniasis in south China was caused by *L. donovani* but this has not been confirmed. In Africa, the infection is largely restricted to Sudan, Ethiopia, and Kenya.

The ecological distribution of *L. donovani* is well known but poorly understood. In Asia, where humans are the only known hosts, the infection occurs in heavily populated rural areas in the rich silty flood-plains of the great rivers. Here, the vector *P. argentipes* is abundant and strictly synanthropic, breeding in the organically rich material on the floors of cow byres, almost the only sandfly whose larval habitat is reasonably well described (Ghosh and Bhattacharya 1991). The only known reservoirs of infection here are humans and persistent cases of PKDL may be particularly important in maintaining the parasite between epidemics (Addy and Nandy 1992).

In Africa, there are two types of habitat, each associated with a specific vector. *P. orientalis* occurs in *Acacia seyal* woodland, which is the dominant natural vegetation of the light, alluvial, montmorillonite, silty clays of eastern Sudan between latitudes 9°N and 14°N, extending into the western Ethiopian lowlands. *P. martini* occurs in less well defined habitats but is commonly associated with eroded termitaria in the heavy laterite clays of the southern borders of Sudan and Ethiopia, northern Uganda, and much of Kenya. *L. donovani* infection occurs either in fairly stable endemic conditions or as violent epidemics throughout the distribution of these two vectors. The Nile grass rat, *Arvicanthis niloticus*, has been found infected in substantial numbers in southern Sudan and may be an important reservoir host, but the shifting distribution of the epidemics and persistence of intensely endemic residual foci, too dangerous to even visit in the transmission season, remain largely unexplained.

Human *L. donovani* infection is endemic in parts of southern Ethiopia, Sudan, and northern Kenya, where most people are exposed to infection at some time during their lives but relatively few become sick (e.g. Zijlstra et al. 1994). An Ethiopian study indicated an exposure rate of c. 11 percent per year, but there were only 2 percent cases of overt disease annually per 100 non-immune individuals (Ali and Ashford 1994). Nearly all adult males and more than half the females showed evidence of previous exposure.

This apparent insusceptibility of most of the people cannot be true of the early epidemics in northwest India where the disease swept through the population like a plague killing a large proportion (and, incidentally, giving rise to the dreadful reputation of malaria: kala-azar was thought to be *the* malignant, lethal form of malaria (Rogers 1908)). The epidemic of the late 1980s in southern Sudan was equally virulent, and was estimated to have killed half of the affected population, some 100 000 people, in 5 years (Seaman et al. 1992).

Epidemics of kala-azar are often associated with natural disasters or social upheavals, although causal relationships are difficult to establish. The work of Sati (1962) documents the spread of an epidemic in Sudan with famine-related displacement. The 1980s Sudan epidemic may have resulted from the introduction of the parasite by people coming from endemic areas on the Ethiopian border to settled areas with potential transmission. These movements were related to the civil war, as was the poor condition of the recipient people, but any precise interpretation is largely informed speculation.

Although epidemics in Africa occur in rural, largely pastoral environments, those in India are in towns and villages with settled agriculture. In the north Bihar epidemic, maximum incidence was estimated at 6 per 1 000 per year, with more than 100 000 cases reported in some years. In 1992, there were 80 000 cases (Sacks et al. 1995). Reported cases are surely only a small fraction of the actual number occurring.

Epidemiology of *L. infantum* infection

L. infantum parasites are difficult to separate objectively from *L. donovani* and the distribution of the two forms is largely allopatric, so there is a good case for regarding them as subspecies. However, it is convenient to treat them separately because they are very distinct in both their ecology and epidemiology.

L. infantum is the only *Leishmania* species that occurs in both the Old and New Worlds (in the Americas it is sometimes called by its junior synonym *L. chagasi*; see New World leishmaniasis for New World features). In the Old World, it is distributed in much of the Mediterranean basin, both in Europe and North Africa (see Figure 2). It extends erratically through Arabia, Turkey, and Iran to the Central Asian republics, Pakistan, and Kashmir (Rab and Evans 1995), as well as into northwest China. It is thought to have been much more widely distributed in China but visceral leishmaniasis has been almost eradicated throughout that country.

Throughout this range, the main host is the domestic dog, which develops an acute or chronic disease. Though eventually fatal, canine visceral leishmaniasis presents abundant parasites in the skin, available for transmission. The distribution of foci of infection depends on the presence of vector sandflies, usually species of the subgenus *Phlebotomus* (*Larroussius*). Although we are ignorant of the mechanisms by which the distribution of sandflies is regulated, each species has clearly defined ecological preferences. *P. ariasi*, for example, is largely restricted to hillsides with mixed oak *Quercus* spp. woodland. A more important vector, *P. perniciosus*, occurs at lower altitudes, in drier, limestone country, where it is particularly abundant in gardens and suburbs with outcrops and dry-stone walls. These are the main vectors in the western Mediterranean; they are replaced

further east by *P. major* and a wide variety of less well studied probable vectors.

In areas where transmission is intense, almost all dogs become infected and kennels become very difficult to keep. Individual dogs vary greatly in their response to infection and there is some evidence that regionally bred dogs are less susceptible than exotic breeds.

Human infection must be very much more common than overt disease. The latter is classically restricted to children, especially those below the age of 2 years. In the post-war years, the incidence in children, though not in dogs, in most of southern Europe has decreased greatly so the small number of adult cases has become a greater proportion of the total (Marty et al. 1994). In fact, adult cases have now actually increased owing to greater susceptibility to disease in association with HIV and immunosuppression associated with transplant surgery.

CHEMOTHERAPY AND TREATMENT

Treatment of leishmaniasis has a chequered history. Few adequate clinical trials have been carried out, especially with cutaneous leishmaniasis; recommended dosages are frequently based on spurious information and definition of the state of the disease is rarely standardized. Patients frequently present at a late stage, having been treated informally with unknown remedies. Courses of treatment are usually prolonged and so are difficult to monitor or even achieve. Despite these misgivings, the various diseases can generally be cured quite effectively, albeit mainly with drugs that come from archaic pharmacopoeia (Chance 1995; Croft and Yardley 2002). In addition to healing the patient, treatment may also reduce the transmission of anthroponotic *L. tropica* or *L. donovani* infection.

Placebo and physical treatment

The first question is whether or not chemical treatment is justified or even required. Simple, single lesions due to *L. major* will heal naturally in a few months and leave the patient immune for life. It is only with multiple or disfiguring lesions that chemotherapy is justified. The same may be said of lesions due to *L. tropica*, though these are of longer duration. With *L. donovani* infection, sick patients have a high risk of death if left untreated, but active case detection may reveal numerous sub-clinical infections. It may be preferable to keep these under observation if possible, especially if, as is frequently the case, resources are very limited.

Cutaneous lesions, whether or not to be treated, should be disinfected and covered, to prevent secondary infection and to avoid infecting sandflies. Heat treatment, with hot compresses or infra-red radiation may accelerate cure. Hot water, in the form of frequent baths or saunas, is beneficial in diffuse cutaneous leishmaniasis, which responds very poorly to chemotherapy. Removal of lesions by cryotherapy has been recommended, but is controversial. For visceral leishmaniasis associated with massive splenomegaly and unresponsiveness to antimonial drugs, surgical removal of the spleen used to be practiced occasionally and has also been undertaken relatively recently (Magill et al. 1994).

Pentavalent antimonials

Pentavalent antimony, currently used in the form of meglumine antimoniate or sodium stibogluconate, replaced tartar emetic many years ago and is still the first line drug of choice (Croft and Yardley 2002). However, increasing incidence of unresponsive infections, now known to be due to genuine parasite drug resistance, means that this may not remain true for much longer (Sundar 2001). Intralesional infiltration is used for simple, single cutaneous lesions but intramuscular injection is required for all other cases. Despite the prolonged period of repeated treatment required for the cure of visceral leishmaniasis, these drugs are remarkably safe if administered in the correct doses; their reputation for toxicity is unjustified and relates rather to the trivalent antimonials used previously (Bryceson 1987b). Antimony is excreted rapidly from the body so doses are repeated daily and treatment is continuous throughout each course.

For visceral leishmaniasis, the World Health Organization (WHO 1995) recommends intramuscular injection of 20 mg Sb^{5+}/kg daily (to a maximum of 850 mg) for a minimum of 20 days, and until no parasites can be seen in spleen or marrow biopsies taken 14 days apart. Doses may be divided to counteract rapid excretion. Relapsing patients should be treated similarly.

For cutaneous leishmaniasis, the World Health Organization (WHO 1995) recommends 1–3 ml of either of the main antimony preparations, to be infiltrated into the base of the lesion, to be repeated once or twice, at intervals of 1–2 days. For parenteral treatment, 10–20 mg Sb^{5+}/kg i.m. is given daily until a few days after clinical cure.

Aromatic diamidines

Pentamidine, as the isethionate or dimethylsulfonate, is used as a second choice in cases that are unresponsive to antimony. This product may, however, have serious toxic effects, due to sensitivity at the site of intramuscular injection, too rapid intravenous injection, accumulation, or overdosage. The drug may disrupt blood-sugar homeostasis and lead to intractable diabetes after prolonged use. The margin between therapeutic and toxic doses is narrow and the drug is only slowly

excreted, so prolonged treatment at well spaced intervals is required.

The World Health Organization (WHO 1995) recommends treatment with 4 mg/kg three times per week for 5–25 weeks, or even longer, for visceral leishmaniasis. For African diffuse cutaneous leishmaniasis, the only other likely use of this drug in Old World leishmaniasis, treatment is once weekly, but continued for at least 4 months.

Monomycin/paromomycin/aminosidine

The antibiotic monomycin was developed in Russia both for intralesional injection and as a topical treatment for cutaneous leishmaniasis. In the latter use, the active ingredient was contained in a collagen pad tightly applied to the lesion. Paromomycin and aminosidine are probably the same as monomycin, and show considerable promise in topical ointments but in current formulations, irritation, and inflammation are too severe for these products to be more than experimental. This antibiotic shows promise as a synergist when used in combination with antimonials, in both visceral and diffuse cutaneous leishmaniasis (Seaman et al. 1993; Teklemariam et al. 1994).

Amphotericin B

In soluble form, this product is too toxic to be used except where all else has failed. It is administered very slowly, by the intravenous route, requires careful monitoring, and the early doses must be reduced in order to check for excessive side-effects. This drug is mainly used to treat cases of mucocutaneous leishmaniasis in South America (see New World leishmaniasis) and is rarely indicated in Old World leishmaniasis. The recommended dose is 0.5–1.0 mg/kg on alternate days (WHO 1995). More recently, however, there have been important developments in the use of amphotericin, with lipid-associated forms of amphotericin (e.g. liposomal encapsulation) showing much reduced toxicity (Chance 1995). These are now commercially available (AmBisome, Amphocil) and, although relatively expensive, are suitable alternatives to antimonials.

Allopurinol

Allopurinol has the attraction that it is a widely used and well-established drug. Furthermore, biochemical and in vitro studies indicate that it should be effective against *Leishmania*. Despite these factors, clinical trials have been disappointing, although there are suggestions that the drug may have a synergistic effect when used together with antimony.

Miltefosine

Miltefosine or hexadecylphosphocholine, is the phosphorylcholine ester of hexadecanol and was originally developed as an anticancer agent but showed activity against experimental visceral leishmaniasis in mice (Kuhlencord et al. 1992). Recent clinical trials using miltefosine against Indian visceral leishmaniasis have been very encouraging (Jha et al. 1999; Sundar et al. 2002). If miltefosine proves to be clinically useful after more extensive testing, it may represent the most significant step forward in leishmanial chemotherapy for some time as, unlike the other treatments for visceral leishmaniasis, the drug is delivered orally. If safe and effective it is likely to become the first line drug of choice in the future.

VACCINATION

Two important factors suggest that vaccination or other immunological intervention holds promise for the protection of people from at least some of the leishmaniases. First, many individuals appear innately not to be susceptible. This is demonstrated by the survival of some people in even the most serious epidemics and by the finding that some individuals, who have never been exposed, produce a lymphocyte proliferation response to antigen (Akuffo and Britton 1992; Kurtzhals et al. 1995). Second, the immunity produced naturally in response to *L. major* infection is usually solid and there is no evidence that it is not sterile. There may even be a cross-immunity between *L. major* and other species. At present, however, no vaccine is available against Old World leishmaniasis.

Immunization against cutaneous leishmaniasis by deliberate infection with virulent parasites is traditional in parts of west Asia and was carried out on a massive scale during the Iran–Iraq war (Nadim 1988). Both the Russian and Israeli armies abandoned this measure as there were an unacceptable number of serious side-effects. Trials are in progress using various crude and recombinant antigen preparations with acceptable adjuvants and it is hoped that vaccination, at least against *L. major* infection, may soon become feasible (Modabber 1995; Handman 1997; McMahon-Pratt et al. 1998; Handman 2001).

INTEGRATED CONTROL

The principles of control, with particular reference to vector control, are discussed in Control of parasites, parasitic infections, and parasitic diseases. Control of infection depends greatly on local information which, in turn, depends on efficient passive case detection and epidemiological surveillance. These are the minimal activities recommended by the World

Health Organization (WHO 1990). Increased knowledge of the structure of foci of leishmaniasis has led to the proposal of numerous potential active control strategies, but few of these have been evaluated or even tried in practice.

Avoidance of areas of risk is the simplest method and could be applied to military or other activities involving entry into semi-arid areas where zoonotic *L. major* can be a serious risk. In North Africa and west Asia, barracks for soldiers or laborers should be situated well away from depressions with halophilic vegetation and *P. obesus* colonies. People infected with HIV should avoid much of southern Europe in summer, although the coast itself is generally free from *L. infantum* infection. The few known residual foci of intense *L. donovani* transmission in Africa should be avoided. Some of the national parks of Sudan are particularly notorious and are rarely visited in the transmission season.

Environmental management, such as the destruction of desert rodent colonies in inhabited areas, has been attempted with great success in central Asian irrigation schemes, the designs of which were modified to prevent reinvasion by *R. opimus*. Pilot schemes to clear land around affected towns in Tunisia (Ben Ismail 1994) and Jordan (Kamhawi et al. 1993) were inconclusive. The incidence of infection can vary greatly from year to year, so experimental controls are hard to establish. In Ethiopia, it has been suggested that villages affected by *L. aethiopica* infection could be protected by shooting the hyraxes in the vicinity, but this intervention has yet to be tried.

In areas where transmission is peridomestic, as with *L. tropica* and *L. donovani* in Asia, sandfly numbers can be greatly reduced by insecticides. In fact, antimalarial campaigns were credited with the near-eradication of kala-azar in India in the 1950s. Active case detection, treatment and insecticide spraying eliminated *L. tropica* in Azerbaijan in the 1960s. A mass campaign in China in the 1950s, using case detection and treatment, insecticides and elimination of dogs, reduced the number of cases from an estimated 500 000 in 1951 to almost zero (Wang 1985; Guan 1991). Experiments with insecticide-impregnated bednets or curtains have given promising results (Maroli and Majori 1991).

Where transmission is sylvatic, as in the *L. donovani* epidemics in southern Sudan, the economic and political problems that prevent effective control elsewhere are compounded by technological problems. There is no realistic way to alter the environment, we know of no way to reduce sandfly numbers, and the reservoir hosts maintaining residual foci have not been identified. Little can be done other than the provision of active case detection and treatment or the promotion of impregnated bednets, with no guarantee that the latter will be effective. These measures are almost impracticable in such a poor, isolated, and war-torn country. Much of northern Sudan has undergone massive environmental change with the replacement of woodland by mechanized agricultural projects. This elimination of much of the *P. orientalis* habitat has incidentally greatly reduced the area in which kala-azar epidemics can be expected to occur.

INTRODUCTION

Neotropical cutaneous leishmaniasis (NCL) seems to be of great antiquity. Pottery from Peru and Ecuador, dated c. AD 400–900, commonly depicted human faces with mutilations that are remarkably similar to those caused by present day cutaneous and mucosal leishmaniasis (Figure 1) and, at the time of the conquistadores, Spanish historians wrote about ugly facial lesions that frequently afflicted the local Amerindians.

The earliest traceable clinical description of the disease is probably that of a certain Dr L. Villar who, in 1859, wrote 'the disease (Peruvian ''uta'') is very like the Aleppo button' (i.e. oriental sore due to *Leishmania tropica*) (Matta 1918).

The first suspicions that phlebotomine sandflies might be involved in the transmission of NCL seem to have been those of Cosme Bueno who, in 1764, implicated these insects in uta in endemic areas; uta is caused by *L. (Viannia) peruviana* in the Peruvian highlands (Herrer and Christensen 1975). Final proof that NCL was due to infection with *Leishmania* was to await publications by Lindenberg (1909) and Carini and Paranhos (1909), who independently demonstrated 'Leishman-Donovan bodies' in the skin lesions of patients from the State of São Paulo, Brazil. It was left to another Brazilian, Gaspar Vianna (1911) to give the name of *Leishmania brazilienses* to the parasite, later corrected to *L. braziliensis* by Matta (1916).

It is quite extraordinary that until 1972, all cases of NCL in Brazil and a number of neighboring countries were attributed solely to this parasite, although specific species names were attributed in different regions: Velez (1913) had given the name *L. peruviana* to the causative agent of Peruvian uta; Biagi (1953) had named the parasite of Mexican chiclero's ulcer as *L. tropica mexicana,* emended to *L. mexicana* by Garnham (1962); and Floch (1954) considered pian-bois in French Guyana to be due to *L. tropica guyanensis,* later emended to *L. braziliensis guyanensis* by the Brazilian parasitologist Pessôa (1961). During the past 30 years, intensive ecological and epidemiological studies in the Americas have revolutionized previous ideas regarding the etiology of NCL and the classification of its causative parasites. No less than 21 species of *Leishmania* are now recognized within the neotropical region, of which 15 are known to cause either cutaneous or mucocutaneous leishmaniasis or both in humans. There is little doubt that others remain to be discovered and described, particularly in the rich sandfly and mammalian faunas of the great South American forests.

Cutaneous leishmaniasis is widespread in Latin America, and the only two countries that seem to be free of the disease are Chile and Uruguay: cases have even been recorded in the extreme south of the USA in Texas, and rodents naturally infected with *L. (L.) mexicana* have been found in Arizona, USA. A reliable figure for the incidence of the human disease in the Americas is virtually impossible to obtain: it is not a notifiable disease in most of the countries where it occurs. Most of these countries also have poor facilities for unequivocal diagnosis so heavy reliance is placed on

Figure 1 *Peruvian pottery (huaco) showing facial mutilations thought to represent mucosal leishmaniasis. (From Pessôa and Barretto 1948)*

clinical aspects, which are often misleading. In Costa Rica, a small country, but with very good communications and medical assistance, the impressive figure has been given of more than 2 000 cases a year in a population of 2 000 000 (Walton 1987). In Brazil, the Ministry of Health reported an increase in the number of cases from 2 856 in 1977 to 4 821 in 1982, (Walton 1987). Lacerda (1994) suggested the considerably higher figure of 154 103 recorded cases between the years 1980 and 1990, with an incidence of c. 5 people in 1 000 infected between the years 1980 and 1984, rising to 25 per 1 000 during 1987–1990.

In all known instances, NCL is a zoonosis: that is, the causative parasites are primarily those of wild animals. When the various sandfly vectors also feed on humans there may be transmission of a number of species of *Leishmania*; in this 'unnatural' host, they usually provoke an intense reaction and the eventual development of a skin lesion at the site of the bite. Some 7–10 days later, a tiny papule appears which, although usually painless, may itch considerably. In most cases, the papule eventually ulcerates, producing a steadily growing and crater-like lesion with a characteristically inflamed, elevated border (Figure 2). A lesion may remain single, but in some cases infected macrophages may transport the parasites to other parts of the body and establish secondary lesions. One parasite in particular, *L. (V.) braziliensis,* tends to produce

Figure 2 *Simple skin lesion of the arm, due to* Leishmania (Viannia) braziliensis*; Pará, Brazil*

such metastatic lesions in the nasal, pharyngeal and laryngeal mucosae. These may arise within a few months of the original skin lesion, or years later when the patient has supposedly been cured of the initial infection; they may be extremely mutilating (Figures 3 and 4).

Other neotropical *Leishmania* species may produce an even more serious and incurable condition in individuals who fail to mount a fully functional cell-mediated immune reaction against the parasite. Such patients, who develop large numbers of nodular lesions scattered over almost the whole skin surface (Figure 5), have been referred to as cases of diffuse cutaneous leishmaniasis (DCL). This is a misleading term as other perfectly curable cases of cutaneous leishmaniasis in immunologically competent patients may have numerous lesions

Figure 3 *Mucocutaneous leishmaniasis, due to* L. (V.) braziliensis*; Pará, Brazil*

Figure 4 *Destruction of the palate, due to* L. (V.) braziliensis*; Para, Brazil*

scattered over the body surface (Figure 6; see also *Leishmania (Viannia) guyanensis* Floch, 1954, below); the term anergic diffuse cutaneous leishmaniasis (ADCL) is more appropriate. In the Americas, this condition has been found associated only with infection by members of the *mexicana* complex, e.g. *L. (Leishmania) mexicana, L. (L.) pifanoi*, and *L. (L.) amazonensis.* In the Old World, another member of the subgenus *Leishmania*, *L. (L.) aethiopica,* causes a similar incurable disease in immunologically incompetent patients (see Old World leishmaniasis).

The fact that a number of *Leishmania* species cause disease in humans in the neotropics is reflected in variations in chemotherapeutic responses. Thus, drugs that work well in one region may not be so efficient in another because the species of the parasite infecting the patients are different. In Guatemala, for example, individuals infected with *L. (L.) mexicana* responded to treatment with ketoconazole better than those infected with *L. (V.) braziliensis* s.l., but the reverse applied when patients were treated with sodium stibogluconate (Navin et al. 1992).

Unlike humans, the natural sylvatic hosts of the various neotropical *Leishmania* species rarely suffer disease from the infection, which is usually of a benign, inapparent nature. Under certain circumstances (see *Leishmania (Viannia) braziliensis* (Vianna, 1911) Matta, 1916), domestic animals such as dogs, mules, and horses may be found with extensive skin ulcers due to *Leishmania:* an indication that they, like humans, are unnatural and unaccustomed hosts.

The known history of American visceral leishmaniasis (AVL) is comparatively short compared with that of the Old World (Old World leishmaniasis). The first record was probably that of Migone (1913), who saw 'corpuscles', which he was convinced were amastigotes of *Leishmania,* in the blood of a sick man in Paraguay. The patient's symptoms were highly indicative of visceral leishmaniasis and, failing to respond to antimalarial treatment, he died. Prior to his illness, the man had been working on the construction of the São Paulo–Corumbá railway in Brazil, where he most probably became infected. The first undoubted cases to be registered in Latin America were documented by Mazza and Cornejo (1926) in two Argentinian children.

Penna (1934) used the viscerotome to examine liver samples from patients suspected to have died from yellow fever in various parts of Brazil. He diagnosed 41 of them as being cases of visceral leishmaniasis, the largest number coming from the north-east of that country. Sporadic cases began to be recorded in Bolivia, Colombia, Guatemala, Paraguay, and El Salvador, but the full importance of the disease as a public health problem was not realized until as recently as 1953, when a dramatic outbreak was estimated to have been responsible for more than 100 deaths in the small country town of Sobral, in the State of Ceará, north-east Brazil (Deane 1956). Clearly, the history of AVL goes back much further than this and deaths from this highly lethal infection must have long been attributed to other causes, including malaria and yellow fever. To this day, AVL remains second in importance only to malaria among the Latin American tropical diseases, with the very conservative number of over 6 000 cases recorded in Brazil alone, up to 1980 (Deane and Grimaldi 1985).

Although a wide variety of *Leishmania* species have been recorded in humans, the prevalence of each of these will clearly depend on just how anthropophilic their respective sandfly vectors are. Thus, by far the

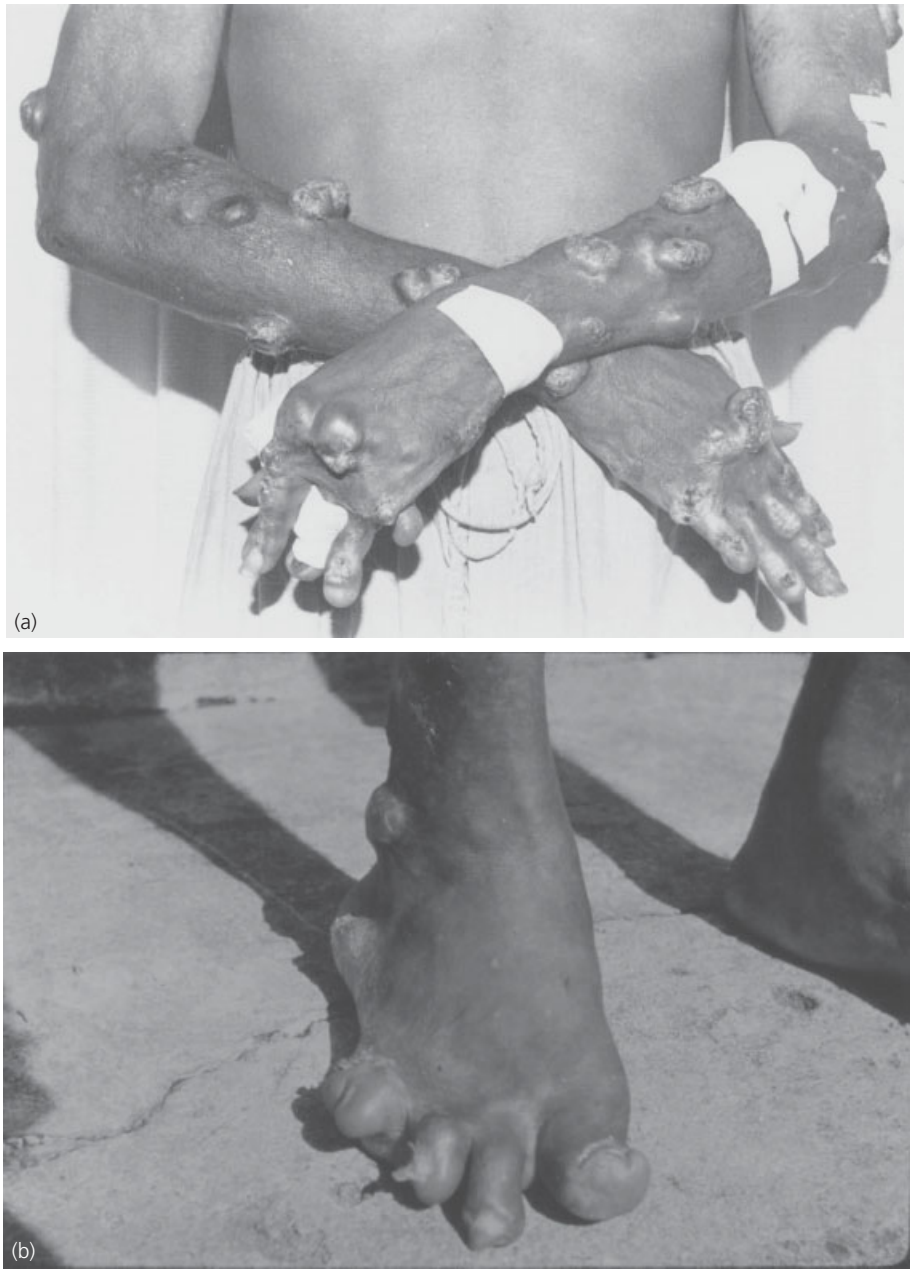

Figure 5 *ADCL due to* L. (L.) amazonensis. *Note the amputation of some fingers* **(a)** *and toes* **(b)**, *simulating lepromatous leprosy, with which disease ADCL is often confused; Pará, Brazil. (Figure 5a from Lainson 1982b)*

largest proportion of NCL cases in Brazil are due to *L. (V.) braziliensis* and *L. (V.) guyanensis*, both of which have sandfly vectors that feed avidly on humans. On the other hand, human infection with *L. (V.) lainsoni* and *L. (V.) naiffi* is relatively rare, as their vectors are disinclined to bite humans. Some neotropical *Leishmania* species, like *L. (L.) hertigi* and *L. (L.) deanei* of porcupines, are unknown in humans, possibly due to their inability to survive in human tissues, but more probably because their sandfly vectors never feed on humans.

It is likely that all neotropical *Leishmania* species once shared a sylvatic ecology, as is still the case in the remaining areas of extensive primary and secondary forest in the Amazon Region. Following the Iberian colonization and ensuing destruction of the forests, some phlebotomine sandfly species adapted to a peridomestic habitat. The persistence of cutaneous leishmaniasis in such ecologically disturbed, although still essentially rural, areas has been taken to indicate the evolution of a secondary, peridomestic transmission of the causative parasite; the occurrence of leishmanial skin lesions in village dogs, mules, and horses suggests that such domestic animals might have now become secondary reservoir hosts. Their development of extensive skin

Figure 6 *Multiple skin lesions due to* L. (V.) guyanensis. *Similar lesions were present on this man's legs, arms and face; Pará, Brazil. (From Lainson 1982b)*

lesions tends to suggest, however, that, like humans, these animals still remain unnatural and unaccustomed 'victim' hosts. Firm evidence is required to show that infected humans, dogs, and equines are capable of infecting sandflies fed on them and thus maintaining the parasite in the absence of another source of infection in wild animals still existing in nearby surviving pockets of woodland. Reithinger and Davies (1999), in a review of the literature, concluded that evidence suggesting the domestic dog as a reservoir for human American cutaneous leishmaniasis was largely circumstantial. This conclusion was supported by Savani et al. (1999) who found no serological evidence of infection in 973 stray dogs examined in an endemic area of cutaneous leishmaniasis in São Paulo State, Brazil. Tolezano et al. (1998) carried out serological surveys of dogs in two endemic areas of the Ribeira River Valley, São Paulo State. It was suggested that dogs played only a minor role in maintaining the parasite population in one area, with only six of 77 (7.8 percent) animals positive to the skin test: in the other area, a positivity of 10 out of 56 (17.9 percent) led to their conclusion that dogs are involved in the maintenance of *L. (V.) braziliensis* to different degrees in different regions of Brazil. Positive skin tests are no indication, however, that the dogs are a source of parasites for the sandfly vector(s).

The role of humans as a source of infection for sandfly vectors of cutaneous leishmaniasis in the Americas remains controversial. The Brazilian parasitologist Aragão (1922) succeeded in infecting *Lu. intermedia* on the skin lesions of patients, and Strangways-Dixon and Lainson (1966) infected six out of eight sandflies *(Lu. cruciata* and *Lu. ylephilator*) by feeding them on the indurated margin of lesions due to *L. (L.) mexicana* in Belize. The fact that sandflies fed on healthy skin of the same patients consistently failed to become infected and that the insects showed a marked reluctance to feed on old, scabbed lesions, led them to conclude that only on rare occasions were humans likely to serve as a reservoir of infection for the sandfly vector. In a similar experiment, Montoya-Lerma et al. (1998) obtained two infected *Lu. longipalpis* out of 103 that took a bloodmeal on the edges of lesions due to *L. (V.) braziliensis*, but none among those that had fed on normal skin of the same patients. Understandably, the systemic nature of visceral leishmaniasis provides a more ready source of amastigotes in the blood of persons with active infections. Costa et al. (2000) fed 3 747 laboratory-bred *Lu. longipalpis* on persons with active, asymptomatic and apparently cured infections, in an area endemic for AVL: 26 flies acquired infection from 11 of 44 persons with active infections, but none of those fed on 137 asymptomatic individuals became infected. This supports the observation of Deane (1956) that man is a poor source of infection compared with the acutely infected dog.

Although *Lutzomyia longipalpis*, the major vector of AVL, is better known as a peridomestic or intra-domiciliary sandfly, its origin is sylvatic (Lainson 1989; Lainson et al. 1990a). In Amazonian Brazil, for example, it has been captured in primary rain forest far from human habitation and when crude roads are cut through such forest, newly constructed houses and animal sheds are soon invaded by this insect. It follows that whether the source of the disease is local foxes (*Cerdocyon thous*), in which the infection rate may be more than 50 percent, or infected dogs brought to the area from distant endemic foci of AVL, transmission of the parasite will ensue and a new focus of the canine and human disease will be established.

Studies on the ecology of the New World leishmanial parasites have strongly suggested the existence of environmental barriers that limit the different species of *Leishmania* to specific sandfly species that transmit to certain mammalian hosts in distinct ecotopes. Extreme care and considerable field research is needed, therefore, before conclusions can be reached as to the principal sandfly vectors of the different parasites. The mere presence of a *Leishmania* in a specimen of a given sandfly species does not necessarily mean that this insect is the vector of that parasite. Before such a conclusion can be reached, the organism must be found with frequency in that particular sandfly and must show

abundant proliferation in the alimentary tract, with migration to the foregut and mouthparts. Ideally, a definite association with the wild mammalian host should be shown to exist and, if the parasite is a cause of human leishmaniasis, the fly must be shown to bite humans.

Similarly, the efficiency of a given mammal in maintaining a *Leishmania* species in nature and in serving as a source of infection for the sandfly vector must be considered. Determining a significant infection rate in the mammalian host and providing experimental proof that the sandfly vector can be infected by feeding on it are prerequisites in labeling the animal as a reservoir host.

A number of the neotropical *Leishmania* species were first described in their wild mammalian or sandfly hosts, considerable time elapsing before they were incriminated as a cause of human leishmaniasis. For this reason, this chapter discusses all the known New World species, regardless of the fact that some have yet to be found in humans. Old World leishmaniasis, deals with the systematic position of the genus *Leishmania*, morphology and development of the organism in the mammalian and sandfly hosts, the application of biochemistry and molecular biology to identification of the different species of the parasite, genetics and immunology, clinical features and the treatment of human cutaneous and visceral leishmaniasis. Many features of these topics are common to both Old World and New World leishmanial parasites and this chapter discusses only those that seem to be peculiar to the American leishmaniases and their causative agents. Lengthy discussions on the evolution, ecology, epidemiology, and classification of the parasites have been given elsewhere (Lainson and Shaw 1979, 1987; Lainson 1983; Lainson et al. 1994; Shaw and Lainson 1987; Shaw 1994), and reviews on the history of the neotropical leishmaniases have also been dealt with in other publications (Lainson and Shaw 1992; Lainson 1996). For methods in the laboratory diagnosis of these diseases, see Lainson and Shaw (1981) and Old World leishmaniasis.

CLASSIFICATION OF THE RECOGNIZED NEOTROPICAL *LEISHMANIA* SPECIES

The genus *Leishmania* has been subdivided into two subgenera, as follows.

The subgenus *Leishmania* Ross, 1903

This subgenus possesses the characteristics of the genus (see Old World leishmaniasis). The life-cycle in the natural sandfly vector is limited to the midgut and foregut of the alimentary tract. Species occur in both the Old World and the New World (type species *Leishmania (Leishmania) donovani* (Laveran and Mesnil, 1903) Ross, 1903 of the Old World). The recorded neotropical species are:

1 *Leishmania (Leishmania) infantum chagasi** Cunha and Chagas, 1937
2 *L. (L.) enriettii* Muniz and Medina, 1948
3 *L. (L.) mexicana** (Biagi, 1953) Garnham, 1962
4 *L. (L.) pifanoi** (Medina and Romero, 1959) Medina and Romero, 1962
5 *L. (L.) hertigi* Herrer, 1971
6 *L. (L.) amazonensis** Lainson and Shaw, 1972
7 *L. (L.) deanei* Lainson and Shaw, 1977
8 *L. (L.) aristidesi* Lainson and Shaw, 1979
9 *L. (L.) garnhami** Scorza et al., 1979
10 *L. (L.) venezuelensis** Bonfante-Garrido, 1980
11 *L. (L.) forattinii* Yoshida et al., 1993.

*Recorded from humans. For distribution, see Table 1.

The subgenus *Viannia* Lainson and Shaw, 1987

This subgenus possesses the characteristics of the genus (see Old World leishmaniasis). The developmental cycle in the natural sandfly vector includes a prolific and prolonged phase of division of rounded or ovoid paramastigotes and promastigotes attached to the wall of the hindgut (pylorus and ileum, see Figure 7) by flagellar hemidesmosomes, followed by migration of free promastigotes to the midgut and foregut. Members of this subgenus are known only in the neotropical region and the recorded species are as follows:

1 *Leishmania (Viannia) braziliensis** (Vianna, 1911) Matta, 1916; type species
2 *L. (V.) peruviana** Velez, 1913
3 *L. (V.) guyanensis** Floch, 1954
4 *L. (V.) panamensis** Lainson and Shaw, 1972
5 *L. (V.) lainsoni** Silveira et al., 1987
6 *L. (V.) shawi** Lainson et al., 1989
7 *L. (V.) naiffi** Lainson and Shaw, 1989
8 *L. (V.) colombiensis** Kreutzer et al., 1991
9 *L. (V.) equatorensis* Grimaldi et al., 1992
10 *L. (V.) lindenbergi** Silveira et al., 2002
11 *L. (V.) utingensis* Braga et al., 2003

*Recorded from humans. For distribution, see Table 1.

Species within the subgenus *Leishmania* Ross, 1903

LEISHMANIA (LEISHMANIA) INFANTUM CHAGASI CUNHA AND CHAGAS, 1937

Known geographical distribution

Distribution has been noted throughout most of the Latin American continent: Argentina, Bolivia, Brazil,

Known mammalian hosts

Known mammalian hosts include humans and the domestic dog, *Canis familiaris*. Among wild animals the fox, *Cerdocyon thous*, appears to be an important natural reservoir in Brazil in the northeast (Ceará), north (Pará), and southeast (Mato Grosso do Sul) (Deane 1956; Lainson et al. 1987; Mello et al. 1988; respectively). Evidence has been presented suggesting that the infected foxes identified by Deane (1956) in Ceará as *Lycalopex vetulus* were most probably *C. thous* (Courtenay et al. 1996).

There are reports of isolates of the parasite from domestic rats in Honduras (Walton, personal communication) and, on rare occasions, from opossums of the genus *Didelphis* in Bahia, northeast Brazil (Sherlock et al. 1984). In Colombia, *D. marsupialis* is considered to be an important reservoir host (Corredor et al. 1989; Travi et al. 1994).

The latter authors (Travi et al. 1998) obtained positive results using the polymerase chain reaction (PCR)-hybridization test for three out of 34 specimens of the 'spiny-rat', *Proechimys canicollis* from forest in Colombia and suggested that these animals had active infections, although no parasites were isolated from them. Continuing their studies on the epidemiology of visceral leishmaniasis in Colombia, Travi et al. (2002) tested the susceptibility of another species of *Proechimys* (*P. semispinosus*) to *L. infantum chagasi* following inoculation of promastigotes by the intracardial and intradermal routes. No parasites could be detected in smears of the viscera from all of the 10 animals when they were sacrificed 7 months later, but positive cultures were obtained from splenic material of two of five animals inoculated by the intracardial route and three of five inoculated by the intradermal route. Attempts to infect sandflies (*Lu. longipalpis*) after two or three xenodiagnoses on each animal, during a period of 1–6 months, all failed: PCR-

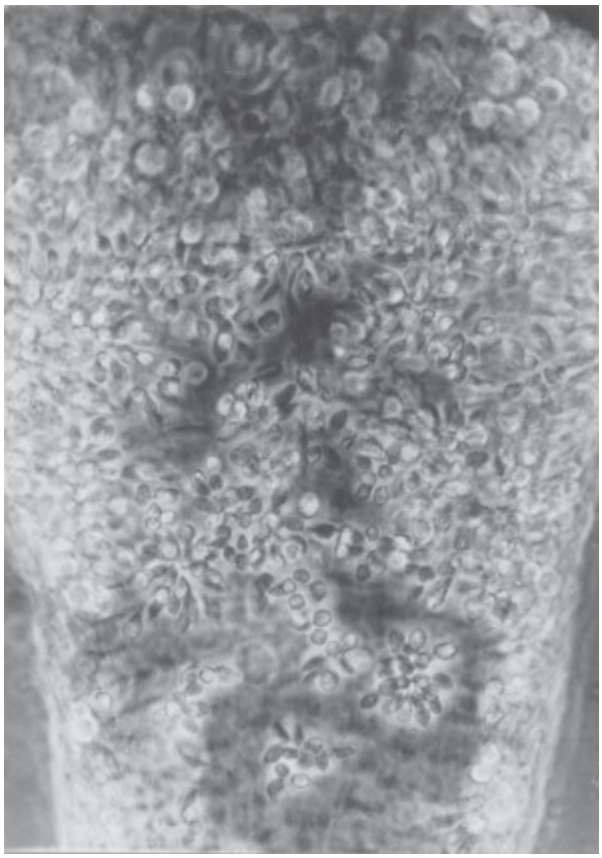

Figure 7 *The pylorus ('hindgut triangle') of a sandfly infected with* L. (V.) braziliensis. *Prolific division of rounded or ovoid promastigotes and paramastigotes attached by flagellar hemidesmosomes to the gut wall, a characteristic of* Leishmania *species within the subgenus* Viannia.

hybridization tests gave negative results. It was concluded that the infection in *P. canicollis* 'is contained and compartmentalized', but that there may be differing degrees of susceptibility among different species of *Proechimys*.

Lainson et al. (2002) attempted to infect 12 laboratory-bred *Proechimys guyanensis* with a strain of *L. i. chagasi* from Amazonian Brazil, by massive intraperitoneal inoculation of amastigotes or promastigotes Although control hamsters succumbed to acute infection 6 months p.i., no infection could be registered in any of the *P. guyanensis* when sacrificed at 6 or 12 months p.i., by stained smears of liver and spleen, culture of these tissues and their inoculation into hamsters, and the PCR-hybridization test. Furthermore, during the experiment laboratory-bred *Lu. longipalpis* showed a complete reluctance to feed on the experimental animals. Based on these results, previous unsuccessful attempts to capture *Lu. longipalpis* in Disney-traps baited with *P. guyanensis* and placed in the backyards of sandfly-infested houses, and a failure to isolate *L. i. chagasi* from large numbers of this rodent captured in foci of AVL in northern Brazil (Lainson et al. 1987), the authors concluded that *P. guyanensis* is an unsuitable host for this parasite and plays no important part in the eco-epidemiology of the disease in north Brazil.

Recorded sandfly hosts

Lutzomyia (Lutzomyia) longipalpis is the major vector of *L. (L.) infantum chagasi* throughout its geographic range (Deane and Grimaldi 1985; Lainson 1989) and the parasite has been transmitted experimentally by the bite of this sandfly, using both laboratory-infected and naturally infected flies (Lainson et al. 1977, 1985). Strong evidence was provided, however, that *Lu. longipalpis* represents a species complex of at least two taxa (Ward et al. 1988), based on slight morphological differences (males with pale spots on terga 3 and 4, versus others with a similar spotted pheromonal gland on only the 4th tergum). Attempts to cross-breed the two forms failed, adding support to this suggestion (Ward et al. 1983). Following a study of population genetics and phylogenetic analyses of *Lu. longipalpis* from Central and South America, Soto et al. (2001) suggested that specific allopatric populations had differentiated to the extent of forming sibling species, with four distinct lineages corresponding to central and northern South America, Brazil and an isolated population in Colombia.

Lanzaro et al. (1993) compared populations of *Lu. longipalpis* from Costa Rica, Colombia and Brazil, using isoenzyme electrophoresis and cross-breeding experiments. They concluded that the three populations represented three different species. This finding has helped to explain why different clinical manifestations of *L. (L.) infantum chagasi* infection in humans occur in some geographic regions (see Clinical features).

In one particular region endemic for visceral leishmaniasis, in the Córdoba Department of Colombia, 87 percent of the sandflies captured were found to be *Lutzomyia evansi* and as one of these flies was infected with *L. (L.) chagasi* it was suggested that this sandfly might be acting as an alternative vector (Travi et al. 1990). In later studies (Travi et al. 1996) infections were found in nine more specimens of *Lu. evansi*, and, taking into account the apparent absence of *Lu. longipalpis* and the peridomestic and intradomiciliary habits of *Lu. evansi*, these authors concluded that this species was the principal vector in that part of Colombia. *Lu. evansi* had long been suspected as an alternative vector of *L. (L.) infantum chagasi* in Venezuela, following failure to find *Lu. longipalpis* in some foci of AVL where *Lu. evansi* was abundant (Potenza and Anduze 1942; Pifano and Romero 1964). The conclusions of these authors have gained strong support from the recent isolation of promastigotes from this sandfly in Venezuela and the finding that k-DNA restriction analysis showed high homologies between the cultures and *L. (L.) infantum chagasi* (Feliciangeli et al. 1999).

In the State of Mato Grosso do Sul, Brazil, suspicions have been raised that *Lu. cruzi* might be another alter-

native vector (dos Santos et al. 1998). Unfortunately, the females of this sandfly are morphologically indistinguishable from those of *Lu. longipalpis* and conclusions were based on an infection in a single female sandfly (*Lu. cruzi* or *Lu. longipalpis*?) and the apparent absence of *Lu. longipalpis* males. The limited geographical distribution of these two 'alternative' vectors compared with that of *Lu. longipalpis*, however, leaves no doubt regarding the overwhelming importance of the latter as the principal sandfly host of *L. (L.) infantum chagasi*.

Disease caused by the parasite in humans

The parasite predominantly causes visceral leishmaniasis, commonly with a fatal outcome unless treated (see Old World leishmaniasis). On rare occasions, the visceral disease may be preceded by a cutaneous lesion, and in some geographical regions the parasite is responsible for an almost exclusively cutaneous disease (see Clinical features). Until recently, only cutaneous lesions were recorded in Costa Rica, but a single case of visceral leishmaniasis has now been recorded (Carrillo et al. 1999). Common names for the visceral disease include kala-azar or calazar but it is more appropriate to reserve these terms for Indian visceral leishmaniasis and to use the name American visceral leishmaniasis or AVL.

Opinions have been divided as to whether the causative agent of AVL is indigenous to the Americas, or whether it is simply *L. (L.) infantum*, which was introduced into the New World by immigrants from the Iberian peninsula in post-Columbian times. Points in favor of the first hypothesis and retention of the specific name *L. (L.) chagasi*, originally given to the parasite, are as follows:

- There is a high incidence of infection in the native fox, *Cerdocyon thous*, in relatively remote areas of Amazonian Brazil and the benign and inapparent nature of these infections is indicative of an ancient host–parasite relationship.
- Wild canids are considered to be the source from which members of the *L. (L.) donovani* complex originated (Lysenko 197l) and canids were present in the Americas as long ago as the Pleistocene era, some 2–3 million years ago.
- *Lu. longipalpis* is a vector of *L. (L.) chagasi* throughout almost the entire geographic range of the parasite, but is not known to transmit any other neotropical species of *Leishmania*; the vectors of *L. (L.) infantum* belong to a different sandfly genus. The host specificity of *Leishmania* species in nature is most pronounced among their sandfly vectors, thus it seems unlikely that introduced *L. (L.) infantum* could have made the relatively sudden jump from one phlebotomine genus to another.
- There are differences in both the kinetoplast DNA fragment patterns and the radio-respirometry profiles of *L. (L.) infantum* and *L. (L.) chagasi* (Jackson et al. 1982, 1984; Decker-Jackson and Tang 1982) and the two parasites are antigenically different (Santoro et al. 1986). The hypothesis that American visceral leishmaniasis is the result of imported *L. (L.) infantum* is based on the similarity of those isoenzyme profiles of the two parasites that have been studied (Rioux et al. 1990), the dual role of the domestic dog as an amplification host in their respective epidemiologies (Killick-Kendrick 1985) and recent studies on the genomic diversity in the *Leishmania donovani* complex (Maurício et al. 1999). The authors of this chapter have long used the name *L. (L.) chagasi*. From the close biochemical and molecular similarities that have now been shown, however, we feel it best to separate the two parasites only at subspecific level, with the names *L. (L.) infantum infantum* and *L. (L.) infantum chagasi*.

LEISHMANIA (LEISHMANIA) ENRIETTII MUNIZ AND MEDINA, 1948

Known geographical distribution

To date, this parasite has been found only in the States of Paraná and São Paulo, Brazil.

Known mammalian hosts

Natural infections have, until now, only been found in domestic guinea-pigs (*Cavia porcellus*). When this strange parasite was first discovered, producing large tumor-like lesions on the ears of two laboratory guinea-pigs (Medina 1946), the origin of the infected animals was obscure. As phlebotomine sandflies are the only known vectors of *Leishmania* species, however, it is difficult to imagine that domestic guinea-pigs are the principal natural hosts of *L. (L.) enriettii*, and it can only be assumed that the animals had spent some time in or near a rural area where transmission was occurring among the true, wild mammalian hosts. There have been two further spontaneous reappearances of the parasite in domestic guinea-pigs, again in Curitiba, Paraná (Luz et al. 1967) and more recently in a rural district of São Paulo State (Machado et al. 1994). Although the exact locality of the animals was on these occasions well documented, attempts to discover the wild animal source of the parasite were not made.

Recorded sandfly hosts

The natural vector of *L. (L.) enriettii* remains to be discovered. Luz et al. (1967) examined the sandfly population of neighboring forest around the site of isolation, where *Lu. monticola* and *Lu. correalimai* were the only species encountered. *Lu. monticola* was caught on tree trunks, in the nests of opossums (*Didelphis*) and from human bait, and six of 10 specimens fed on the lesions of guinea-pigs became heavily infected.

Absence of infection in humans

Human infection has not yet been reported. Muniz and Medina (1948) attempted to infect human volunteers, rhesus monkeys, dogs, mice, and the wild guinea-pig (preá) by the intradermal inoculation of promastigotes from in vitro cultures, without success. Out of eight hamsters inoculated, only one developed an inconspicuous lesion containing scanty amastigotes. Failure to infect the closely related wild guinea-pig (*Cavia aperea*) at first seems surprising. Lainson and Shaw (1979) suggested, however, that if this animal is the natural host of *L. (L.) enriettii* the inoculated preá may well have developed an inapparent infection that went unnoticed.

LEISHMANIA (LEISHMANIA) MEXICANA (BIAGI, 1953) GARNHAM, 1962

Known geographical distribution

The areas of known geographical distribution are Southern USA (Arizona and Texas), Mexico, Belize, Guatemala, Honduras, and Costa Rica. In view of extensive geographic separation from the type locality of *L. (L.) mexicana* and considerable differences in the mammalian and phlebotomine sandfly faunas, reports of this parasite in Panama and some South American countries must be viewed with caution.

Known mammalian hosts

The known mammalian hosts are humans and the forest rodents *Ototylomys phyllotis* (primary host), *Nyctomys sumichrasti*, *Heteromys desmarestianus* and *Sigmodon hispidus* (secondary hosts). In southern USA, the rodent *Neotoma albigula* has been found infected in Pima County, Arizona.

Recorded sandfly hosts

Lutzomyia olmeca olmeca is the only proven vector, but *Lu. (Lu.) diabolica* has been suspected as a vector in foci of cutaneous leishmaniasis due to *L. (L.) mexicana* in southern Texas and northern Mexico, and *Lu. anthophora* in Arizona.

Disease caused by the parasite in humans

This parasite causes cutaneous leishmaniasis, with a pronounced tendency towards long-lasting and destructive lesions of the external ear (Figure 8). Relatively rare cases of ADCL have been recorded, principally from southern Texas and northern Mexico. Local names include chiclero's ulcer, chiclero's ear, and bay-sore.

Parasites clearly related to *L. (L.) mexicana* have been reported from humans and wild animals in Panama, Colombia, Venezuela, Peru, and parts of Brazil. In the absence of the vector, *Lu. olmeca olmeca,* it is perhaps unlikely that any of these are true *L. (L.) mexicana*.

Figure 8 *Chiclero's ulcer, due to* L. (L.) mexicana. *Almost total destruction of the the external ear in a chiclero from Belize with an infection of many years' duration. (From Lainson and Strangways-Dixon 1963)*

Sandflies of the *Lu. flaviscutellata* complex, to which subspecies of *Lu. olmeca* belong, range through these South American countries, however, and are probably the vectors of a number of closely related parasites within the *mexicana* complex: at present this includes *L. (L.) pifanoi*, *L. (L.) amazonensis*, *L. (L.) aristidesi*, *L. (L.) garnhami*, *L. (L.) venezuelensis* and *L. (L.) forattinii*.

LEISHMANIA (LEISHMANIA) PIFANOI (MEDINA AND ROMERO, 1959) MEDINA AND ROMERO, 1962

Known geographical distribution

Known distribution is limited to Venezuela, specifically in the States of Yaracuy, Lara and Miranda.

Known mammalian hosts

Humans are the only known mammalian host: the wild mammalian hosts of the parasite have yet to be discovered. A parasite isolated from the forest rodent *Heteromys anomalus* was shown to behave in hamsters in the same way as *L. (L.) pifanoi* isolated from humans, but its conclusive identification remains in doubt.

Recorded sandfly hosts

A parasite with similar characteristics was also found in a specimen of *Lu. flaviscutellata* but, once again, has not been conclusively identified. This sandfly is the proven vector of *L. (L.) amazonensis*, another member of the *mexicana* complex often found in rodents in South American forests and it remains likely that the Venezuelan workers were dealing with this parasite.

Disease caused by the parasite in humans

All isolates found to date have been from cases of ADCL. It is most likely, however, that simple, curable lesions also occur in immunologically competent

individuals. There has been much controversy regarding the validity of this member of the *mexicana* complex, some authors regarding it merely as an enzymic variant of either *L. (L.) amazonensis* or *L. (L.) mexicana*. Much confusion has certainly resulted from the laboratory mix-up of parasites. Although there are relatively few isolates of *L. (L.) pifanoi*, interest in the clinical features of the human infection has resulted in a wide distribution of the parasite to laboratories throughout the world.

LEISHMANIA (LEISHMANIA) AMAZONENSIS LAINSON AND SHAW, 1972

Known geographical distribution

The parasite has been recorded in Bolivia, Brazil, Colombia, French Guyana, and Paraguay. It is also very likely to occur in other South American countries where the sandfly vector is found.

Known mammalian hosts

Known mammalian hosts are the forest rodents *Proechimys* (principal host), *Oryzomys*, *Neacomys*, *Nectomys*, and *Dasyprocta*; the marsupials *Marmosa*, *Metachirus*, *Didelphis*, and *Philander*; and the fox *Cerdocyon*.

Recorded sandfly hosts

The principal vector of the parasite is *Lutzomyia (Nyssomyia) flaviscutellata*. Occasional infections have been found in the closely related flies *Lu. (N.) olmeca nociva* and *Lu. (N.) reducta* but, if these are capable of transmitting the parasite, they probably play a small role in its ecology and epidemiology. In Bolivia, a parasite identified as *L. (L.) amazonensis* has been isolated from 16 of 1 715 *Lu. nuneztovari* dissected (Martinez et al. 1999).

Disease caused by the parasite in humans

The parasite causes cutaneous leishmaniasis, usually of the single sore type and ADCL in individuals with a defective cell-mediated immune system (Figures 5 and 9). If it does occur, classical mucocutaneous leishmaniasis following metastasis to the nasopharyngeal mucosae from a simple cutaneous lesion is extremely rare. In advanced cases of ADCL, however, the disseminated infection may also include those tissues.

Typical visceral leishmaniasis in patients from one particular region of Bahia State Brazil, has been attributed to *L. (L.) amazonensis* (Barral et al. 1986). Conversely, no records exist to confirm this anywhere else in the geographical range of the parasite and cases of ADCL of very long duration show no signs or symptoms of visceral involvement, in spite of their defective immune system. Silveira examined the tissues from a patient who suffered from ADCL due to *L. (L.) amazonensis* from the age of 5 years until his death at the age of 57 years (Figure 5a) (F.T. Silveira, unpublished observations). At the time of his death, scarcely any of his body surface remained unaffected and the cutaneous lesions contained enormous numbers of parasites (Figure 10). No macroscopic or microscopic pathological changes were seen in the viscera and no amastigotes were found in stained impression smears prepared from the spleen, liver and lungs, and bone marrow. Finally, hamsters inoculated intradermally with triturates of these visceral tissues failed to become infected.

Figure 9 *ADCL due to* L. (L.) amazonensis *in a young woman from Pará, Brazil, showing active lesions and extensive scarring of the legs in an infection of some 15 years' duration.*

LEISHMANIA (LEISHMANIA) ARISTIDESI LAINSON AND SHAW, 1979

Known geographical distribution

The parasite is known to occur in the Sasardi forest, San Blas Territory, Eastern Panama.

Known mammalian hosts

Known mammalian hosts are the rodents *Oryzomys capito*, *Proechimys semispinosus*, and *Dasyprocta punctata*; and the marsupial *Marmosa robinsoni*.

Recorded sandfly hosts

The species most suspected is *Lutzomyia (Nyssomyia) olmeca bicolor*. Christensen et al. (1972) showed it to be

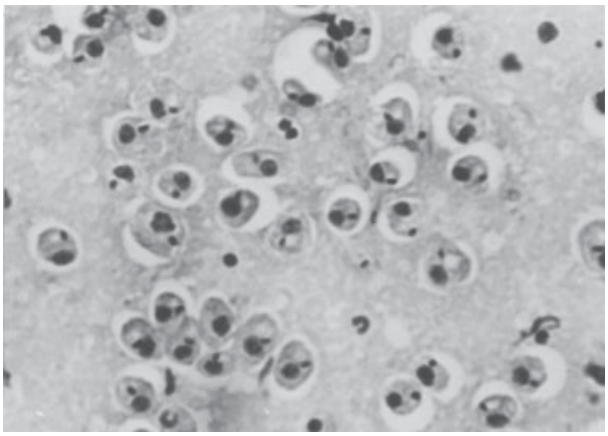

Figure 10 *Amastigotes of* L. (L.) amazonensis *in a Giemsa-stained smear from one of the nodular lesions of the patient shown in Figure 5a.*

the dominant fly on Disney-traps baited with rodents and opossums in the area where infected animals had been captured and the most common species collected among leaf litter on the forest floor.

Possibility of infection in humans

Human infection has not yet been reported. *Lu. olmeca bicolor* does bite humans on rare occasions and it is likely that the parasite may eventually be found infecting a human. In this respect, it should be remembered that following the discovery of *L. (V.) naiffi* in armadillos in 1979, 11 years were to pass before cases of human cutaneous leishmaniasis due to this parasite were diagnosed (Lainson et al. 1979, 1990b; Naiff et al. 1989).

LEISHMANIA (LEISHMANIA) GARNHAMI SCORZA ET AL., 1979

Difference of opinion exists regarding the validity of *L. (L.) garnhami*, which is indistinguishable from *L. (L.) amazonensis* on isoenzyme profiles (Rioux et al. 1990). Guevara et al. (1992), however, noted clear differences between the nontranscribed rDNA intergenic spacer sequences of these two parasites and, in our own laboratory, they have been separated by monoclonal antibodies (Shaw, Ishikawa, and Lainson, unpublished observations).

Known geographical distribution

The parasite has been found only in the Venezuelan Andes.

Known mammalian hosts

Humans are known hosts and a single infection has been recorded in the marsupial *Didelphis marsupialis*.

Recorded sandfly hosts

Experimental infections in the sandfly *Lu. youngi* (*verrucarum* group) in Venezuela have led some authors to suggest this species to be the vector (Grimaldi et al. 1989; Young and Duncan 1994; Killick-Kendrick 1990). In addition, Scorza (in Màrquez and Scorza 1982) reported that he had found natural infections with flagellates in *Lu. youngi* (at the time identified as *Lu. townsendi*) that, on inoculation into the skin of hamsters, produced 'amastigotes de *Leishmania garnhami*'. Unfortunately, the parasite was not specifically identified and the role of *Lu. youngi* as the vector still remains in doubt.

Disease caused by the parasite in humans

The parasite causes cutaneous leishmaniasis, but there are no recorded cases of mucocutaneous leishmaniasis or ADCL.

LEISHMANIA (LEISHMANIA) VENEZUELENSIS BONFANTE-GARRIDO, 1980

Known geographical distribution

The parasite has been found in the Lara and Yaracuy States, Venezuela.

Known mammalian hosts

The known mammalian hosts are humans, equines, and the domestic cat. These are best regarded as 'victim' hosts and the wild animal source of infection has yet to be ascertained.

Recorded sandfly hosts

Lu. olmeca bicolor and *Lu. rangeliana* are suspected as possible vectors.

Disease caused by the parasite in humans

The parasite causes single or multiple skin lesions, sometimes of a disseminated, nodular type simulating ADCL but curable by the current method of antimonial treatment.

LEISHMANIA (LEISHMANIA) FORATTINII YOSHIDA ET AL., 1993

Known geographical distribution

The parasite has been found in the States of São Paulo, Bahia and Espirito Santo, Brazil.

Known mammalian hosts

The opossum *Didelphis marsupialis aurita* (São Paulo) and the rodent *Proechimys iheringi denigratus* (Bahia

and Espirito Santo, Brazil) are the known mammalian hosts.

Recorded sandfly hosts

The sandfly vector is unknown. Barretto et al. (1985) showed experimentally that the parasite was capable of development in the sandflies *Psychodopygus ayrozai* and *Lutzomyia yuilli* from the Três Braços area, Bahia, where the two insects are very common.

Possibility of infection in humans

The parasite has not yet been reported to cause human disease. Both *Ps. ayrozai* and *Lu. yuilli* occasionally feed on humans and if one or other of these sandflies is indeed the vector among the wild animal hosts, human infection with *L. (L.) forattini* may well occur.

Species within the subgenus *Viannia* Lainson and Shaw, 1987

These parasites have been separated by their isoenzymatic profiles, the use of monoclonal antibodies, and their biological characteristics. As is clear from Supplement 1 to volume 96 of *Trans R Soc Trop Med Hyg*, molecular biology techniques are now important tools in the field of parasitology and a set of microsatellite markers has recently been developed that enables separation of all known species of *Leishmania* within the subgenus *Viannia* and also indicates possible species hybrids (Russell et al. 1999). It will be particularly useful in the detection and identification of the more closely related pair *L. (V.) braziliensis* and *L. (V.) peruviana*, and the trio *L. (V.) panamensis*, *L. (V.) guyanensis* and *L. (V.) shawi*. A rapid method for the identification of *Leishmania* species using formalin-fixed biopsy samples and PCR is another promising new development (Mimori et al. 1998), as is the claim that these parasites can be reliably detected and identified, at least to the *L. (V.) braziliensis* complex level, by PCR using boiled dermal scrapings instead of skin biopsies (Belli et al. 1998).

LEISHMANIA (VIANNIA) BRAZILIENSIS (VIANNA, 1911) MATTA, 1916

Known geographical distribution

The distribution of this important parasite is badly defined, due to inadequate methods of identification used in the past. Parasites variously described as '*L. braziliensis*', '*L. braziliensis braziliensis*' or '*L. braziliensis* sensu lato' have been reported from most Latin American countries, including Argentina, Belize, Bolivia, Brazil, Colombia, Costa Rica, Ecuador, French Guyana, Guatemala, Honduras, Mexico, Nicaragua, Panama, Paraguay, Peru, Surinam, and Venezuela.

Environmental factors seem to govern the combinations of sandfly vector and wild mammalian host in the natural history of the different species of *Leishmania*. It seems unlikely, therefore, that *L. (V.) braziliensis* sensu stricto can have such an enormous geographic range and the parasites recorded in many of these regions may represent related, but different, parasites of the *braziliensis* complex. The situation is aggravated by the fact that the type material of *L. (V.) braziliensis* Vianna, 1911 from Além Paraiba, Minas Gerais, Brazil, is no longer available for comparison. It is further complicated by distinctly different ecological and epidemiological features of cutaneous and mucocutaneous leishmaniasis due to *L. (V.) braziliensis* s.l. in different regions, sometimes within the same country, due to human destruction of the sylvatic habitat. Finally, a high degree of enzymic polymorphism has been shown to exist in isolates of *L. (V.) braziliensis* s.l. from Central and South America, with as many as 44 zymodemes obtained in a total of 137 isolates examined by 10 enzyme systems (Chouicha et al. 1997). In a similar manner, a variety of different serodemes have been shown to exist in the parasite from Brazil (Shaw et al. 1986).

Known mammalian hosts

In primary forest in the Serra dos Carajás, Pará State, Brazil, the low-flying habit and high attraction of the principal sandfly vector to both humans and rodent-baited traps led to the conclusion that terrestrial mammals, such as rodents, were probably hosts of *L. (V.) braziliensis* (Ward et al. 1973; Lainson et al. 1973). Subsequent records of parasites considered as this species in the Brazilian rodents *Oryzomys concolor, O. capito*, *O. nigripes*, *Akodon arviculoides*, *Proechimys* spp., *Rattus rattus* and *Rhipidomys leucodactylus*, and the opossum *Didelphis marsupialis* did much to support this suggestion (Forattini et al. 1972, 1973; Lainson and Shaw 1970, 1979; Lainson et al. 1981a; Rocha et al. 1988). In Venezuela, records have been given for the rodents *R. rattus* and *Sigmodon hispidus* (De Lima et al. 2002). In most cases, identification of the parasite was based on only biological features and the isolates are no longer available for confirmation by modern biochemical methods, monoclonal antibodies or molecular techniques. Recently, however, a definitive identification of isolates from the Brazilian rodents *Bolomys lasiurus* and *R. rattus* as *L. (V.) braziliensis* by multilocus enzyme electrophoresis (Brandão-Filho et al. 2003) does suggest that the earlier records of rodent hosts of *L. (V.) braziliensis* were probably correct. It now remains to show that these animals serve as an efficient source of infection for the sandfly vectors.

Domestic animals such as dogs, mules, horses, and (very rarely) cats have been found with skin lesions produced by parasites regarded as *L. (V.) braziliensis* s.l. or simply recorded as leishmanias of the *braziliensis*

complex. These reports, in areas of suspected peridomestic transmission of the parasite, come principally from localities of extensive deforestation in Argentina, southern Brazil, Bolivia, Colombia, and Venezuela.

Recorded sandfly hosts

Uncertainties regarding the exact distribution of *L. (V.) braziliensis* make it difficult to indicate its vector (or vectors). An isolate of the parasite responsible for human cutaneous leishmaniasis in primary Amazonian rain forest in the Carajás highlands of Pará State, Brazil, has been used as a reference strain of *L. (V.) braziliensis* (MHOM/BR/1975/M2903) and in this area the vector is undoubtedly *Psychodopygus wellcomei*. This sandfly, referred to by some as *Lutzomyia (Psychodopygus) wellcomei*, has been found heavily infected on numerous occasions (Lainson et al. 1973) and *L. (V.) braziliensis* has been experimentally transmitted to a hamster by the bite of a naturally infected specimen (Ryan et al. 1987).

Ps. wellcomei is essentially sylvatic and avidly feeds on humans, not only at night but also in the daylight hours during overcast weather. It is extremely abundant in the rainy season (November–April), when it may represent c. 65 percent of the total catch of some 25 different species of sandflies taken off human bait. Captures of sandflies from humans stationed at different heights on tree-ladders have shown that *Ps. wellcomei* has a vertical flight range of only 1–2 meters above ground level: this, and the insect's abundance (25.5 percent) in catches of different sandflies taken from rodent-baited traps, suggest that the principal wild mammalian hosts of *L. (V.) braziliensis*, in the area in question, are likely to be terrestrial animals, probably rodents.

In the lowland regions of Pará State, a parasite identified as *L. (V.) braziliensis* was isolated from a single specimen of a closely related and highly anthropophilic sandfly, *Ps. complexus* (de Souza et al. 1996). The females of this species are morphologically indistinguishable from those of *Ps. wellcomei*, but the males of each species are quite distinct.

In the State of Amazonas another highly anthrophilic species, *Ps. carrerai*, has been found infected with *L. (V.) braziliensis* s.l. (Grimaldi et al. 1989). The strain was biochemically similar to *L. (V.) braziliensis* of humans from the same region but antigenically different from those from other areas of Brazil, including the lower Amazon region.

In other parts of Brazil, occasional isolates of *L. (V.) braziliensis* s.l. have been made from the sandfly *Lutzomyia (Nyssomyia) whitmani* sensu stricto, caught in and around houses in rural parts of Bahia and Ceará States, north-east Brazil (Hoch et al. 1986; Ryan et al. 1990; de Queiroz et al. 1994) and in the States of São Paulo and Minas Gerais (south-east Brazil) it is again suspected as a vector due to its highly anthropophilic feeding habits and its high density in and around human dwelling places and animal sheds in the endemic areas of cutaneous leishmaniasis. In the northern part of Paraná *Lu. whitmani* was shown to form 62 percent of the sandfly population captured, and to be highly anthropophilic. Of 1 628 specimens dissected, three were infected (0.2 percent) and in each case the isolated parasite was identified as *L. (V.) braziliensis* on enzyme profiles using the standard World Health Organization (WHO) reference strains for comparison (Luz et al. 2000).

In the State of Rondônia, Brazil, a parasite identified as *L. (V.) braziliensis* has been isolated from three specimens of *Lutzomyia davisi* (Grimaldi et al. 1991). This sandfly is also highly anthropophilic.

Lutzomyia (Nyssomyia) intermedia is another highly anthropophilic sandfly that, although originally sylvatic, has now adapted well to a peridomestic habitat in deforested, rural areas. It is highly suspected as a vector of *L. (V.) braziliensis* s.l. in the State of Rio de Janeiro and some parts of the State of São Paulo, Brazil and certain regions of Argentina. Flagellates thought to have been promastigotes of *Leishmania* were on one occasion seen in histological sections of the intestines of the sandflies *Lutzomyia migonei* and *Lu. (Pintomyia) pessoai* caught in endemic areas of cutaneous leishmaniasis in São Paulo State (Pessôa and Barretto 1948). Their true nature, however, remains obscure.

In Bolivia *L. (V.) braziliensis* s.l. has been isolated from *Ps. carrerai carrerai* (Le Pont et al. 1988), *Ps. llanosmartini*, and *Ps. yucumensis* (Le Pont and Desjeux 1986), whereas in Colombia (Young et al. 1987) and Venezuela (Young and Duncan 1994) similar parasites have been found in *Lu. spinicrassa*. In north central Venezuela, parasites isolated from *Lu. ovallesi* and *Lu. gomezi* have been typed as *L. (V.) braziliensis* and these sandflies are considered as primary and secondary vectors, respectively, on epidemiological grounds (Feliciangeli et al. 1994). In the Andean region, there is strong evidence that *Lu. youngi* is the vector of local cutaneous leishmaniasis, but the parasites encountered in this sandfly require precise identification. *Lu. spinicrassa* may be a vector throughout areas bordering the endemic Colombian foci.

Disease caused by the parasite in humans

The parasite causes cutaneous leishmaniasis, usually with one or few lesions and also mucocutaneous and mucosal leishmaniasis (Figures 2–4). Common names include:
úlcera de Bauru, ferida brava, ferida sêca, bouba, buba, nariz de anta (tapir nose), and espundia.

The various zymodemes of *L. (V.) braziliensis* s.l. are placed in the *braziliensis* complex, together with the closely related parasite *L. (V.) peruviana*.

LEISHMANIA (VIANNIA) PERUVIANA VELEZ, 1913

Known geographical distribution

The parasite has been noted in Peru, on the western slopes of the Andes and in the inter-Andean valleys. Its range may possibly extend into the Argentinian highlands and it is probably more widely distributed in the Andean countries than previously suspected. Transmission seems to take place in relatively barren, mountainous areas with scant vegetation and a relatively restricted wild mammalian fauna.

Known mammalian hosts

Until recently humans and dogs (*Canis familiaris*) were the only known mammalian hosts (Herrer 1951) The role of the dog in the epidemiology of the human disease has remained obscure, however, and it has long been postulated that both humans and dogs are merely 'victim hosts' of a parasite maintained in wild animals of the Peruvian Andes. Recent studies (Llanos-Cuentas et al. 1999) report that isolations of a parasite from two specimens of the rodent *Phyllotis andinum* and an opossum, *Didelphis marsupialis* have been characterized as *L. (V.) braziliensis* by their isoenzyme profiles. Five other isolates from the rodent *Akodon* sp., were identified only to the subgenus *Viannia*. That the prevalence in the wild animals is much the same as in dogs, supports the existence of enzootic disease in wild animals.

Recorded sandfly hosts

Lutzomyia (Helcocyrtomyia) peruensis and *Lutzomyia verrucarum* have long been suspected as probable vectors, in view of their anthropophilic feeding habits. Isolation of a parasite with the biological characteristics of *L. (V.) peruviana* from the former fly, captured in an endemic area, implies its involvement in transmission (Herrer 1982), but much research in the field is needed before significant evidence can be obtained.

Disease caused by the parasite in humans

The parasite causes simple cutaneous leishmaniasis, not associated with the mucocutaneous disease. It is particularly frequent in school children, commonly resulting in extensive facial scars. Ulcers are usually self-healing and a firm immunity to reinfection with the same parasite is usually imparted. Common names include uta, tiaccaraña and llaga.

LEISHMANIA (VIANNIA) GUYANENSIS FLOCH, 1954

Known geographical distribution

This is an essentially sylvatic species that is an extremely common cause of human cutaneous leishmaniasis, particularly in Brazil, north of the Amazon river and the Guyanas. Its range is reported to also extend into Colombia, Ecuador, Venezuela, and the lowland forests of Peru.

Known mammalian hosts

Known mammalian hosts include humans and, in primary forest, the major reservoir hosts are the sloth *Choloepus didactylus* and the lesser anteater *Tamandua tetradactyla* (Xenarthra) (Lainson et al. 1981b; Gentile et al. 1981) with occasional infections found in rodents and opossums (Lainson et al. 1981a; Gentile et al. 1981) The infection is always inapparent, with parasites located in apparently normal skin and in viscera such as the spleen and liver.

Recorded sandfly hosts

The principal vector among wild animals and to humans is the sandfly *Lutzomyia (Nyssomyia) umbratilis*, with infections relatively infrequently found in a closely related fly, *Lu. (N.) anduzei* and *Lu. (N.) whitmani* s.l. Some early records of the parasite in the latter sandfly in Amazonian Brazil, possibly refer to *Leishmania (V.) shawi.*

Lu. (N.) umbratilis is a sandfly that dwells in the forest canopy and on the larger tree trunks. During the early hours of daylight, it may be found in large numbers resting on the larger tree trunks from which the flies will readily fly off and attack humans when disturbed. Although infection of this sandfly clearly takes place when it feeds on the reservoir hosts at night in the canopy, transmission to humans is principally during the day (early morning), when gangs of forest laborers are engaged in their work, particularly deforestation. Others at risk include the collectors of Brazil nuts and other fruits, topographers, visiting botanists and zoologists, and even the occasional tourist.

The enzootic of *L. (V.) guyanensis*, as studied in primary rain forest, is unlikely to survive in secondary forests or man-made plantations of non-indigenous trees. The small girth of young trees provides a microhabitat that is unsuitable for resting sandflies due to the low surface humidity of the smooth trunks. In addition, such immature trees are an equally unsuitable environment for relatively large and heavy animals, such as sloths and anteaters. Finally, in monoculture plantations (e.g. pine and gmelina) sloths are deprived of their normal diet of indigenous fruits and foliage.

Cutaneous leishmaniasis due to *L. (V.) guyanensis* may reach high prevalence in human communities situated in or very near primary forest, leading to an erroneous impression that the sandfly vector, *Lu. (N.) umbratilis*, has adapted to a peridomestic habitat. There is, as yet, no evidence that this occurs and peridomestic acquisition of the disease is doubtless due to infected flies that have been attracted to the lights of houses at night, from nearby forest. Esterre et al. (1986) showed

experimentally that clearing forest to c. 500 meters from a village situated in primary forest in French Guyana completely interrupted the transmission of *L. (V.) guyanensis* among its inhabitants.

The marsupial *Didelphis marsupialis* has rarely been found infected with *L. (V.) guyanensis* in primary forest where there is intensive transmission of the parasite among sloths and anteaters and to humans. Strangely, however, a high rate of infection has been recorded in the abnormally large populations of this opossum that are attracted to human refuse in villages on the borders of virgin forest (Arias and Naiff 1981). Reasons for this are not clear, nor is it certain whether opossums serve as a source of *L. (V.) guyanensis* for the sandfly vector, or if they merely represent dead-ends in the life-cycle of the parasite.

Disease caused by the parasite in humans

The parasite causes cutaneous leishmaniasis, very frequently with multiple skin lesions (Figure 6). Cases of mucocutaneous disease appear to be rare. Common names for the disease include pian-bois, bosch-yaws, and forest-yaws.

Multiplicity of the skin lesions arises in two very different ways. First, sloths are rather sedentary animals and an infected animal may remain in a given spot for a considerable period. The infection rate of *Lu. (N.) umbratilis* resting on neighboring tree trunks will thus tend to rise to a high level, with levels as high as 25 percent found among many hundreds of specimens taken from a single tree. It follows that people attacked by sandflies in the area may receive numerous infective bites at the same time on all exposed parts of the body. Forest workers tend to be shirtless and frequently wear shorts: for this reason many patients present with lesions scattered over the face, trunk, arms, and legs (Figure 6). The developing multiple lesions of such individuals tend to be of a similar size and evolution. Secondly, there is abundant clinical evidence indicating the formation of metastatic lesions in persons originally presenting with a single skin lesion. These lesions tend to follow a distinct migratory course along the lymphatics and because of this evolution they are frequently nodular and, when ulcerated, of very unequal size.

L. (V.) guyanensis gives its name to the *guyanensis* complex of closely related parasites including *L. (V.) panamensis* and *L. (V.) shawi*.

LEISHMANIA (VIANNIA) PANAMENSIS LAINSON AND SHAW, 1972

Known geographical distribution

As the name suggests, most information on this parasite comes from Panama and the Canal Zone, where the very frequent acquisition of cutaneous leishmaniasis by American military personnel prompted intensive eco-epidemiological studies. It is also recorded in west and central Colombia, Ecuador, Venezuela, Costa Rica, Honduras, and Nicaragua.

Known mammalian hosts

Humans are a host to the parasite. The eco-epidemiology of *L. (V.) panamensis* follows a very similar pattern to that of *L. (V.) guyanensis*, which is not surprising in view of the close biological and biochemical relationship of the two parasites. The major host is the two-toed sloth *Choloepus hoffmanni* with occasional infections reported in the three-toed sloth *Bradypus infuscatus* and *B. griseus* (Herrer et al. 1973). More rarely, infections have been registered in other sylvatic animals such as *Bassaricyon gabbi*, *Nasua nasua* and *Potos flavus* (Carnivora: Procyonidae), *Aotus trivirgatus*, and *Saguinus geoffroyi* (Primates: Cebidae and Callitrichidae) and *Heteromys* (Rodentia). Hunting dogs occasionally develop skin lesions due to *L.(V.) panamensis*: like humans they are 'victim hosts' that rarely, if ever, serve as a source of parasites for the sandfly vector(s), or as a means of maintaining the enzootic.

Recorded sandfly hosts

The major sandfly vector is considered to be *Lu. (N.) trapidoi*, whereas *Lu.(N.) ylephiletor*, *Lu. (Lu.) gomezi*, and *Psychodopygus panamensis* may act as secondary vectors (Johnson et al. 1963; Christensen et al. 1969)

Disease caused by the parasite in humans

The parasite usually causes single or a limited number of skin lesions. Rare cases of mucocutaneous leishmaniasis have been attributed to *L. (V.) panamensis*.

Studies on populations of *Leishmania* in Ecuador have shown a cluster in which the isoenzyme profile of 6-phosphate gluconate dehydrogenase (6PGD) showed considerable variation (Bañuls et al. 1999). As it is this enzyme that has been extensively used to separate *L. (V.) panamensis* and *L. (V.) guyanensis*, these authors suggested that these parasites are not separate species. Within the cluster of these species in eastern Amazonia, however, *L. (V.) guyanensis* strains all grouped together, while isolates from Ecuador grouped with *L. (V.) panamensis* markers. For this reason, and taking eco-epidemiological and clinical data into consideration, we prefer to maintain specific separation of the two parasites.

LEISHMANIA (VIANNIA) LAINSONI SILVEIRA ET AL., 1987

Known geographical distribution

Until recently, this parasite was recorded only in the State of Pará, north Brazil. Its presence has now been noted, however, in forested areas of Peru and Bolivia (Lucas et al. 1994; Martinez et al. 2001). It probably exists in other regions where the known mammalian and sandfly hosts coexist.

Known mammalian hosts

Humans are a known mammalian host. The only known host among wild animals is the rodent *Agouti paca* (Rodentia: Dasyproctidae) (Silveira et al. 1991a).

Recorded sandfly hosts

Lu. (Trichophoromyia) ubiquitalis is a known host and the first representative of the subgenus *Trichophoromyia* to be incriminated as a vector of a *Leishmania* species.

L. (V.) lainsoni was isolated only from this sandfly, among many other species dissected in forested areas where patients had become infected with this parasite (Silveira et al. 1991b). The puzzling fact remained that *Lu. (T.) ubiquitalis* had not been caught biting humans in the forest. It was found, however, that this sandfly would feed avidly on humans if maintained for some hours in the laboratory after capture and this prompted the conclusion that under certain conditions it must also feed on humans in its natural habitat. Continuing field studies confirmed this (Lainson et al. 1992), although the factors influencing the sandfly's biting habits remain obscure. *Lu. (T.) ubiquitalis* is clearly not particularly fond of human blood, which accounts for the relatively low rate of infection with *L. (V.) lainsoni* in humans, compared with other species of *Leishmania*, such as *L. (V.) braziliensis* and *L. (V.) guyanensis*; these have highly anthropophilic sandfly vectors. In Bolivia, promastigote infections have been recorded in the sandfly *Lu. velascoi*, but the parasite was not isolated for characterization. As this fly is the only species of the subgenus *Trichophoromyia* in a region where *L.(V.) lainsoni* was encountered infecting man, it remains highly likely that it is the local vector of this parasite (Martinez et al. 2001).

Disease caused by the parasite in humans

The parasite causes cutaneous leishmaniasis, usually with a single ulcerating skin lesion. Cases of mucocutaneous leishmaniasis due to this parasite have not yet been encountered.

LEISHMANIA (VIANNIA) SHAWI LAINSON ET AL., 1989

Geographical distribution

To date, the parasite has been found in various localities in the Amazon Region of north Brazil, south of the Amazon river.

Known mammalian hosts

Humans are commonly infected. Hosts among the forest animals include the monkeys, *Cebus apella* and *Chiropotes satanas* (Cebidae); the sloths *Choloepus didactylus* and *Bradypus tridactylus* (Xenarthra); and the coatimundi *Nasua nasua* (Procyonidae) (Lainson et al. 1988, 1989). It remains likely that other arboreal animals harbor the parasite.

Recorded sandfly hosts

Infections have so far been recorded in only one species of sandfly, which was provisionally identified as *Lutzomyia (Nyssomyia) whitmani* (Lainson et al. 1989). Morphometric differences have been noted, however, between this insect and the type material of *Lu. (N.) whitmani* sensu stricto from Bahia, northeast Brazil. These, and separation by DNA probes, suggested the vector to be a 'cryptic' species of a *Lu. (N.) whitmani* complex (Rangel et al. 1996). A recent phylogenetic analysis of the described mitochondrial (cytochrome b) haplotypes of *Lu. whitmani*, however, disputes this hypothesis, and suggests the existence of clades of haplotypes and a continuum of interbreeding populations of *Lu. whitmani* in the rain-forest regions of Brazil (Ishikawa et al. 1999). The differences in behavior of the fly in the type locality in Bahia, northeast Brazil, and that in Pará State, north Brazil are nevertheless striking. The former is highly anthropophilic, abundant in human dwelling places, and transmits *L. (V.) braziliensis*; the latter rarely bites man, until now has not been recorded in houses even when these are situated very close to the fly's normal habitat in primary forest, and is a vector of *L. (V.) shawi*.

Disease caused by the parasite in humans

The parasite causes cutaneous leishmaniasis, usually with a single ulcerating skin lesion, but cases of multiple lesions of varying pathologies have been observed (Figure 11). Cases of mucocutaneous leishmaniasis due to this parasite have not yet been encountered.

LEISHMANIA (VIANNIA) NAIFFI LAINSON AND SHAW, 1989

Known geographical distribution

Isolates of the parasite are registered in the Brazilian States of Pará and Amazonas and in French Guyana. The range of this parasite will almost certainly extend into other parts of Latin America where the wild animal host and the sandfly vector coexist.

Known mammalian hosts

Humans are a known mammalian host (Lainson et al. 1990b). To date, the only known wild animal host is the nine-banded armadillo, *Dasypus novemcinctus* (Xenarthra: Dasypodidae), in which there is a high infection rate in apparently normal skin and viscera.

Figure 11 *Strange multiple nodules on the foot due to* L. (V.) shawi*, clinically resembling mycotic disease; Pará, Brazil*

Recorded sandfly hosts

Most recorded sandfly infections (Arias et al. 1985; Naiff et al. 1989) involve the sandfly *Psychodopygus ayrozai* which is, therefore, most suspected as the vector among armadillos. This fly is not highly anthropophilic, which possibly accounts for the paucity of human infection with *L. (V.) naiffi*. On the other hand, the parasite has, on rarer occasions, also been found in *Ps. paraensis* and *Ps. s. squamiventris*, both of which are highly anthropophilic and possibly involved in transmission to humans. Further studies are clearly necessary to establish the respective roles of these three sandflies in the eco-epidemiology of *L. (V.) naiffi*.

Disease caused by the parasite in humans

The parasite causes cutaneous leishmaniasis, usually with single, small, ulcerating lesions. No case of mucocutaneous leishmaniasis has yet been attributed to this parasite.

Unlike most species of *Leishmania*, *L. (V.) naiffi* rarely produces a visible lesion when inoculated into the skin of hamsters, although the parasite may be re-isolated following culture of skin from the inoculation site in blood agar media after at least 1 year. For this reason, human infection with this parasite may have remained undiagnosed in the past, when inoculation of hamsters has been the sole method of isolation attempted from human skin lesions. In addition, it may be that *L. (V.) naiffi* can also produce an occult, benign infection in the skin of humans, as it does in the hamster and that transmission to humans is more frequent than has been suspected.

LEISHMANIA (VIANNIA) COLOMBIENSIS KREUTZER ET AL., 1991

Known geographical distribution

The parasite exists in Colombia, Panama, and Venezuela, probably extending into the neighboring forests of Brazil, the Peruvian lowlands, and other Latin American countries where the wild mammalian and sandfly hosts coexist.

Known mammalian hosts

The parasite has been recorded in humans and the sloth, *Choloepus hoffmanni* (Panama).

Recorded sandfly hosts

Lutzomyia (Helcocyrtomyia) hartmanni has been found infected in Colombia and *Lu. (Lutzomyia) gomezi* and *Psychodopygus panamensis* in Panama (Kreutzer et al. 1991).

Disease caused by the parasite in humans

The parasite causes single to multiple ulcerating skin lesions. Cases of mucocutaneous leishmaniasis caused by the parasite have not yet been seen. The strain identified from Venezuela by Delgado et al. (1993) was isolated from a bone marrow aspirate of a patient with visceral leishmaniasis. It is, however, uncertain whether or not this was the parasite responsible for the clinical symptoms observed.

LEISHMANIA (VIANNIA) EQUATORENSIS GRIMALDI ET AL., 1992

Known geographical distribution

The parasite exists along the Pacific coast of Ecuador.

Known mammalian hosts

The sloth, *Choloepus hoffmanni*, and the squirrel, *Sciurus granatensis* have been identified as hosts. In both animals, the parasite was isolated from the liver and spleen but was not found in the skin.

Recorded sandfly hosts

Lutzomyia hartmanni has been found infected in Ecuador (Furuya et al. 1998).

Disease caused by the parasite in humans

As yet, the parasite has not been found in humans.

LEISHMANIA (VIANNIA) LINDENBERGI SILVEIRA ET AL., 2002

Known geographical distribution

At present, this recently described parasite has been recorded only from degraded forest on the outskirts of Belém, Pará State, north Brazil, with isolates made from a number of soldiers who acquired their infections while undertaking maneuvers in this forest at night.

Known mammalian hosts

Humans are the only recorded host so far. From the behavior of the suspected vector and the circumstances in which the soldiers became infected, the wild animal host(s) is (are) most likely terrestrial.

Recorded sandfly hosts

Lutzomyia (Nyssomyia) antunesi is by far the most common sandfly avidly biting man in the type locality. It is of particular interest that the infected soldiers spent much of their time in slit-trenches, so that their heads and resting arms were at ground level: most of their lesions were on these parts of the body. Previous workers recorded heavy promastigote infections in three specimens of *Lu. (N.) antunesi* from Marajó island, near Belém (Ryan et al. 1984), but they failed to identify the parasite. Its development in the sandfly gut was described as being 'suprapylarian in nature' (i.e. characteristic of the subgenus *Leishmania*), whereas Silveira et al. (2002) clearly showed the development of *L. (V.) lindenbergi* to be peripylarian in experimentally infected laboratory-bred *Lu. longipalpis*.

Disease caused by the parasite in humans

Localized cutaneous lesions: as yet, no cases of mucosal lesions have been recorded. *L. (V.) lindenbergi* is distinguished from other members of the subgenus *Viannia* by its enzyme profiles and the use of monoclonal antibodies. It is clearly closely related to *L. (V.) naiffi* and also produces an inapparent infection in the skin of hamsters.

LEISHMANIA (VIANNIA) UTINGENSIS BRAGA ET AL., 2003

Known geographical distribution

As yet, this parasite is recorded only from the Utinga forest, on the outskirts of Belém, Pará State, north Brazil.

Known mammalian hosts

At present, mammalian hosts are unknown, but given the habits of the vector are likely to be arboreal.

Recorded sandfly hosts

The parasite was isolated from a single specimen of the sandfly *Lutzomyia tuberculata*. This sandfly is commonly found on the larger tree-trunks of primary and secondary forests.

Disease caused by the parasite in humans

Not yet found infecting humans. As the vector shows no tendency to bite man, human infections with *L. (V.) utingensis* are unlikely to occur by way of this insect. If any anthropophilic sandflies are also hosts of the parasite, however, human infection may well be found in the future.

'Hybrid' *Leishmania* of the subgenus *Viannia*

Strains with phenotypic and genotypic characters of two species have been recorded in different geographical areas of Latin America. There are two possible interpretations for such strains: either they represent strains that originated directly from a common ancestor or they are the result of genetic exchange.

L. (V.) BRAZILIENSIS/*L. (V.) PANAMENSIS* HYBRID

Known geographical distribution

The parasite has been found in northern Nicaragua (Darce et al. 1991) close to the border with Honduras. To the south, the strains are *L. (V.) panamensis* and to the north, *L. (V.) braziliensis*. Bañuls et al. (1997) recorded what appears to be the result of hybridization between *L.(V.) braziliensis*/*L.(V.) panamensis* and *L. (V.) panamensis*/*L. (V.) guyanensis* in isolates from human infections in Ecuador.

Known mammalian hosts

So far, the parasite is only known in humans.

Recorded sandfly hosts

No sandfly host has been recorded to date.

Disease caused by the parasite in humans

The parasite causes ulcerating skin lesions. Cases of mucocutaneous infections have not yet been seen.

L. (V.) BRAZILIENSIS/*L. (V.) GUYANENSIS* HYBRIDS

Known geographical distribution

In Venezuela, the parasite has been found in Lara State; Tachira; DF, El Junquito; and Miranda, Guarenas. The isolates from the last three localities were similar, and their hybrid alleles differed from those of the isolate previously made in Lara (Bonfante-Garrido et al. 1992; Delgado et al. 1997).

Known mammalian hosts

So far, the parasite has only been recorded from humans.

Recorded sandfly hosts

No sandfly hosts have yet been found.

Disease caused by the parasite in humans

The parasite causes ulcerating skin lesions. Cases of mucocutaneous leishmaniasis caused by this parasite have not yet been seen.

L. (V.) BRAZILIENSIS/*L. (V.) PERUVIANA* HYBRID

Known geographical distribution

To date, four strains have been isolated from patients in the Limapampa region of the Huanuco Valley, Peru (Dujardin et al. 1995).

Known mammalian hosts

Humans are the only known mammalian host to date.

Recorded sandfly hosts

No sandfly vectors have been recorded.

Disease caused by the parasite in humans

Ulcerating skin lesions were noted in all patients and one also had a mucosal lesion.

Leishmania-like parasites of uncertain taxonomic position

Molecular studies suggest that the following parasites are more closely related to *Endotrypanum* (an intra-erythrocytic flagellate of sloths) than they are to *Leishmania*. Until more information is available, however, we feel it best to retain their present names.

LEISHMANIA (LEISHMANIA) HERTIGI HERRER, 1971

Known geographical distribution

The known distribution is limited to Panama and Costa Rica.

Known mammalian hosts

The tree-porcupine *Coendou rothschildi* is the only known mammalian host.

Recorded sandfly hosts

The sandfly vector of the parasite has still to be discovered. The remarkably high infection rate of 88 percent found in the porcupines studied suggests a close association of the vector with the mammalian host, possibly in the hollow trees where these animals live.

Absence of infection in humans

Human infection has not been recorded. *L. (L.) hertigi* seems to be specific to *Coendou rothschildi*, as the parasite has not been found in a wide variety of other forest mammals studied in the Panamanian forests. The apparent absence of human infection may be due to the failure of the parasite to survive in human tissues, or because the sandfly vector does not bite humans.

L. (L.) hertigi is included in the *hertigi* complex, together with another closely related parasite of porcupines, *L. (L.) deanei*.

LEISHMANIA (LEISHMANIA) DEANEI LAINSON AND SHAW, 1977

Known geographical distribution

The parasite has been noted only in Amazonian Brazil.

Known mammalian hosts

The known mammalian hosts are the tree-porcupine *Coendou p. prehensilis* and another, as yet unnamed, species of *Coendou*.

Recorded sandfly hosts

The vector of *L. (L.) deanei* remains to be discovered. As with *L. (L.) hertigi*, the infection rate in Brazilian porcupines is very high, again suggesting a close association of the vector with the mammalian host, probably in the animal's home in hollow trees. A tree-inhabiting sandfly, *Lu. (Viannamyia) furcata*, taken from a tree-hole in which an infected porcupine was living, was shown to have promastigotes of *L. (L.) deanei* in its midgut (Miles et al. 1980). There was, however, no evidence of migration of the parasites to the anterior station of the gut and, in subsequent experimental infections of this sandfly, it was shown that the promastigotes

disappeared following complete digestion of the blood-meal (Lainson and Shaw 1987).

Absence of infection in humans

Human infection has not been recorded. As with *L. (L.) hertigi*, this could be because the sandfly vector is not attracted to humans or because the parasite cannot survive in human tissues.

L. (L.) deanei, like *L. (L.) hertigi*, seems to be restricted to species of the porcupine *Coendou* and an exhaustive examination of other animals in areas of forest where porcupines are commonly infected failed to indicate any other mammalian hosts (Lainson and Shaw, unpublished observations). Although both parasites seem to be peculiar to porcupines, they are readily distinguishable by their isoenzyme profiles and the morphology of their amastigote stages; those of *L. (L.) hertigi* are strangely elongated and measure from 3.5 × 1.2 to 4.8 × 2.5 μm. The amastigotes of *L. (L.) deanei* are the largest of all known species of *Leishmania*, measuring from 5.l × 3.1 to 6.8 × 3.7 μm.

Working with 12 isolates of *L. (L.) deanei* from Pará, north Brazil, Miles et al. (1980) found that they were separable into groups by the enzyme profiles of:

- malate dehydrogenase (oxaloacetate-decarboxylating) (NADP) E.C.1.1.1.40 (ME)
- phosphoglucomutase E.C.2.7.5.1. (PGM)
- malate dehydrogenase E.C.1.1.1.37 (MDH).

Whether or not this is indicative of a third species of *Leishmania* in the *hertigi* complex is debatable and further study is indicated on the biology, biochemistry and molecular biology of the two zymodemes.

Questionable leishmanial parasites

LEISHMANIA HERRERI ZELODÓN ET AL. 1979

This parasite was isolated in Costa Rica from the sloth *Bradypus griseus* and regarded as a new species of *Leishmania*. Mention was made that the DNA buoyant densities and enzyme profiles of the organism were 'totally different from other known hemoflagellates', but no details of the biochemistry were given and, until further isolates of the parasite are available, there must remain considerable doubt as to its true nature.

Infection of human skin by nonleishmanial amastigotes

Amastigotes found in skin lesions of individuals infected with human immunodeficiency virus (HIV) and non-infected individuals on the Island of Martinique have been considered to be those of monoxenous insect flagellates (Boisseau-Garsaud et al. 2000). It is likely that some such lesions have, in the past, been wrongly attributed to *Leishmania*.

GENETICS

The New World *Leishmania* have 20–25 chromosomes that exhibit high degrees of intra- and interspecies size polymorphism. This is thought to reflect a high level of genomic plasticity. Leishmanial genomic DNA is composed of repetitive, moderately repetitive and unique sequences that, respectively, form ca. 25, 13, and 60 percent of the total. Repeated sequences are useful for identification regardless of their distribution, function or copy numbers. Fernandes et al. (1994) found that the mini-exon repeat units of four *Viannia* species were different. Considerable genomic differences have been noted between the two subgenera, but they appear greater for species of *Viannia*. Mendoza-León et al. (1995) found that the β-tubulin gene regions showed a much greater degree of heterogeneity within and between parasites of the *braziliensis* complex than those of the *mexicana* complex. This suggests that there are more random mutations in the former than in the latter. The same gene may be located in more than one chromosome. This may be the result of gene duplication and transposition to another chromosome or chromosomal duplication followed by size divergence (Spithill and Samaras 1985). A useful summary of the recent developments from the *Leishmania* genome project have been given by Myler and Stuart (2000).

Genetic exchange between neotropical *Leishmania* has not been demonstrated experimentally, but the finding of apparent hybrids among *Viannia* species suggests that it may occur. Hybrids only occur in some localities and it is possible that ecological conditions may be important in determining the contact between the species involved. No hybrids have been noted among neotropical species of the subgenus *Leishmania*. Extreme care is needed in the characterization of flagellates from sandflies, as they may sometimes harbor more than one parasite. Monoxenous flagellates, species of *Trypanosoma*, and *Endotrypanum* will contribute to confusion, in addition to the possible coexistence of two species of *Leishmania* in the same insect, as recorded by Barrios et al. (1994). Ideally, all isolates should be carefully cloned, especially if showing unusual characteristics by current methods of identification.

The possible role in humans of genes and chromosome regions suggested by previous studies in mice to be linked to disease resistance or susceptibility to visceral leishmaniasis has been investigated in 638 individuals in 89 families with multiple cases of AVL in northeast Brazil, using complex segregation analyses (Blackwell 1998). Preliminary results indicated that the major histocompatibility complex showed only weak association with AVL; that there is no evidence for linkage between *nramp1* (the positionally cloned candidate for a murine

macrophage resistance gene) and susceptibility to AVL; and that the T helper 2 cytokine gene cluster is not linked to human susceptibility for this disease. It is suggested that the mouse model, together with knowledge of human response to infection, may lead to identification of important candidate gene regions in humans. Feitosa et al. (1999), used complex segregation analyses in a study of the intradermic reaction to antigens derived from *L. i. chagasi* in 502 individuals from 94 families in Bahia State, northeast Brazil. They concluded that the results gave evidence of a major genetic mechanism, with a frequency of a recessive susceptibility gene (q) of approximately 0.45, and that a small multifactorial component (H = 0.29), acting in combination with a major recessive gene (q = 0.37) could be a concomitant factor.

Viral infections in *Leishmania*

Virus-like particles have been described in the cytoplasm of cultured promastigotes of five isolates of *L. (L.) hertigi* and three of *L. (L.) deanei* (Molyneux and Killick-Kendrick 1987). Although unidentified, they were shown to be associated with cytopathological changes in the mitochondrion of the promastigote. The number of virus-like particles was drastically reduced when *L. (L.) hertigi* were grown as amastigotes in mouse peritoneal macrophages and dog sarcoma cell lines incubated at 32°C. The particles were not transmissible to other *Leishmania* species, nor to cell lines susceptible to viruses.

RNA virus particles belonging to the family Totaviridae were described by Tarr et al. (1988) in cultured promastigotes of a strain of *L. (V.) guyanensis* from French Guyana. Subsequent studies revealed the presence of similar viruses in promastigotes of 11 *Leishmania* strains isolated from humans, including both *L. (V.) guyanensis* and *L. (V.) braziliensis* from the Amazonian region of Brazil and Peru (Guilbride et al. 1992). All the viral isolates are considered to be different and are classified within a single genus, *Leishmaniavirus*. None, however, has been given specific status within this genus. The virus-bearing promastigotes were those of *Leishmania* isolated from uncomplicated cases of cutaneous leishmaniasis, but so far the viral particles have not been demonstrated in amastigotes from the skin lesions. The effect that such viruses may have on the *Leishmania* is not known but in experimental infections of *Leishmania major* in mice, it was noted that an infected line was less pathogenic than an uninfected one.

When human biopsy material from some cases of cutaneous leishmaniasis from Peru were examined for the presence of *Leishmaniavirus* RNA by the reverse transcription polymerase chain reaction (RT-PCR), two samples showed RT-PCR bands of the expected size. Sequence analysis indicated them to share approximately 90 percent sequence with the neotropical strain LRV 1-4 of that virus (Saiz et al. 1998).

CLINICAL FEATURES

American visceral leishmaniasis

Throughout most of its geographical range, the clinical features of AVL closely resemble those of infantile visceral leishmaniasis caused by *L. (L.) infantum* of the Old World (see Old World leishmaniasis) and this similarity extends to the fact that the disease is seen mainly in children (Figure 12). However, It has been shown that the same parasite may produce almost exclusively nonulcerative cutaneous lesions in Costa Rica (Zelodón et al. 1989), and may cause both visceral and cutaneous disease in the same focus of AVL in Honduras and Nicaragua (Ponce et al. 1991; Belli et al. 1999).

The saliva of *Lu. longipalpis* has been shown to contain a potent vasodilatory peptide, maxadilan (Lerner et al. 1991). It was found that when sandflies from Brazilian, Colombian, and Costa Rican populations were fed on the arms of volunteers, the degree of erythema was highest for the Brazilian flies, slightly less for the Colombian, and very low for the Costa Rican examples (Warburg et al. 1994). These authors considered this difference to be due to a variation in the *potency* of the peptide but similar recent experiments have suggested it to be due to differences in the *amount* of maxadilan in the saliva of the three populations (Yin et al. 2000). This is in agreement with the distribution of atypical cutaneous leishmaniasis due to *L. i. chagasi*, and lends credence to the involvement of maxadilan in visceralization of the parasite.

There is evidence that *L. (L.) infantum chagasi* may produce a benign, inapparent infection in some individuals and that severity of the disease depends to some extent on the nutritional state of the infected person (Badaró et al. 1986). Differential diagnosis has to be made principally from malaria, schistosomiasis, cirrhosis of the liver, visceral syphilis and other causes of hepatosplenomegaly.

Although serological methods such as the indirect fluorescent antibody, dot-enzyme-linked immunosorbent assay (ELISA) and direct agglutination tests are useful indicators, the novel use of a dipstick (InBios International, Inc) based on recombinant RK 39 antigen for the differential diagnosis of AVL from other sympatric endemic diseases, has been shown to be rapid and highly specific (Delgado et al. 2001). Also, new latex agglutination test (KATEX) is claimed to detect leishmanial antigen in the urine of patients with a 100 percent specificity (Attar et al. 2001). Unequivocal diagnosis of the disease, however, depends on the demonstration of amastigotes in stained smears of aspirates from the spleen, bone marrow or lymph glands. Usually, such smears contain abundant parasites; if not, the material can be cultured in a suitable blood agar medium (varieties of Novy, MacNeal, Nicolle (NNN) medium).

Figure 12 *AVL, due to* L. (L.) infantum chagasi, *in a boy from Marajó island, Pará, Brazil. Note the greatly distended abdomen resulting from hepatosplenomegaly.*

However, some difficulty may be experienced in culturing the parasite, especially when the aspirates contain scanty amastigotes. The intraperitoneal inoculation of aspirates into hamsters is by far the most reliable method of isolating *L. (L.) infantum chagasi* for further study but the long delay before parasites are detectable in these animals makes the method impractical for quick diagnosis. The PCR, together with specific hybridization techniques, will probably be the method of choice in the future (Noyes et al. 1996; Rodriguez et al. 1997; Breniere et al. 1999), at least in the larger and better-equipped hospitals, clinics, and research laboratories. Traditional methods of demonstrating the presence of the parasite will remain vitally important for many more years to come, however, particularly in the more remote rural areas where the majority of cases are concentrated.

Cutaneous leishmaniasis

Simple cutaneous lesions are produced by 12 of the 14 neotropical species of *Leishmania* known to infect humans. It is not possible, however, to diagnose the causative species by the appearance of these lesions, which are in many cases indistinguishable from the classical leishmanial lesion of the Old World, forming a rounded, crater-like ulcer with a raised border (see Old World leishmaniasis, and Figure 2).

In addition, the simple lesion may vary greatly in appearance (Figures 11 and 13–15), evoking such descriptions as framboesiform, lichenoid, lupoid, nodular, vegetative, verrucose, ulcerative, etc. from clinicians and dermatologists. All of these forms have in common that they are painless; unfortunately, this means that the infected person often fails to seek medical advice until the lesion has reached large proportions. Differential diagnosis needs to consider tropical ulcer (painful and suppurative), sporotrichosis, cutaneous tuberculosis, yaws, blastomycosis, lupus, and tertiary syphilis. Bacterial infections of insect bites or skin abrasions are frequently misdiagnosed as early lesions due to *Leishmania* and are particularly common in children living in rural areas with an abundance of biting flies, such as *Simulium* and *Culicoides*.

Although patients under examination may show a positive Montenegro (leishmanin) skin-test, this may be due to a previous, subsequently eliminated infection with *Leishmania* and may be unrelated to present skin lesions. The demonstration of amastigotes in stained smears prepared from the border of the lesions and

Figure 13 *Infection with* L. (L.) amazonensis, *on the elbow; Pará, Brazil*

Figure 14 *A large number of small, papular satellite lesions surrounding the larger, primary lesions in a case of pian-bois due to* L. (V.) guyanensis*; Pará, Brazil*

isolation of the parasite in blood agar culture medium are prerequisite for diagnosis.

Vacuum aspiration of amastigotes in material from human lymph nodes, first used in the examination of patients with visceral leishmaniasis, has been used in cases of cutaneous leishmaniasis resulting from *L. (V.) braziliensis* infection in Brazil (Marzochi et al. 1993; Romero et al. 1999). Aspiration directly into the culture medium, through the rubber cap, greatly reduces the risk of bacterial or fungal contamination.

Figure 15 *Another atypical lesion, due to the same parasite; Pará, Brazil*

Mucocutaneous and mucosal leishmaniasis

For excellent general reading on this unique form of leishmaniasis, reference should be made to Pessôa and Barretto (1948), Marsden (1986), and Walton (1987).

Although the disease has, on rare occasions, been attributed to *L. (V.) guyanensis* and *L. (V.) panamensis*, the great villain is undoubtedly *L. (V.) braziliensis* s.l. The exact percentage of individuals infected with this parasite who develop mucosal lesions is difficult to calculate. In what was almost certainly a hospital series in São Paulo State, southern Brazil, Pessôa (1941) produced figures indicating that among 171 patients with cutaneous lesions of less than 1 year's duration, 105 lacked mucosal lesions and 66 (38.5 percent) had mucosal involvement. Of 110 individuals with cutaneous lesions of more than 1 year's duration, 21 had no mucosal lesions, and 89 (80.9 percent) had developed them. Marsden (1986), however, described Pessôa's figure of 80.9 percent as 'widely quoted out of text ... giving the impression that the great majority (of cases) will proceed to mucosal metastasis'.

In field studies in an endemic area in Três Braços, Bahia State, north-east Brazil, Marsden and his colleagues found only 2.7 percent of 371 patients examined to have both cutaneous and mucosal lesions. Mucosal infection seems to be much more common in some Latin American countries (e.g. Bolivia and Ecuador) than in others, suggesting that certain parasites referred to as *L. (V.) braziliensis* have a greater propensity for producing mucosal lesions than others (these may, in fact, represent different subspecies, or even species, of the *braziliensis* complex).

In spite of its antiquity, the most detailed study of the mucosal lesions remains that of Klotz and Lindenberg (1923), but a wealth of clinical and pathological data is also available in the works mentioned above, and that of Ridley (1987). It is generally agreed that involvement of the mouth, nose, and throat is always the result of metastases from a simple skin lesion elsewhere on the body (Figure 2). Apparently, migration of the parasites to the mucosae, by way of the lymphatics or the bloodstream, may take place quite early in the infection, for amastigotes have been demonstrated in scrapings of the apparently normal nasal mucosae of 12 patients with skin lesions of only 1–11 months' evolution (Villela et al. 1939). The nose is the major site of the metastases (Figure 3) and it remains a mystery as to why this occurs in some individuals and not in others. From the observations of Villela et al. and the fact that years may elapse between the disappearance of the primary skin lesion and the onset of mucosal disease, it seems that the parasite remains dormant in the mucosae for a variable period. Exactly what triggers this occult infection into destructive activity is another mystery, although minor

injury to the mucosae may be one cause. The following account of the developing pathology of the mucosal disease is summarized from Ridley (1987).

When a nasal lesion develops, it is initiated in the deep mucosa of the nose, an accumulation of plasma cells and lymphocytes forming around the small blood vessels. A few amastigotes may appear in the endothelial cells. The major part of the lesion stays in the deep mucosa, accompanied by congestion and edema, a pronounced infiltration of plasma cells and a characteristic proliferation of the vascular endothelial cells, which contain variable numbers of amastigotes. Inflammatory foci proceed towards the mucosal surface, resulting in a patchy desquamation, followed by hyalinization and necrosis of the exposed tissue, accompanied by polymorph infiltration. It should be stressed that the ulcer is due to the desquamation resulting from the inflammatory process and not to the necrosis. In the area of deep inflammation, the endothelial nodule, with its perivascular inflammatory cells, undergoes central necrosis or, in the case of large nodules, hyalinization. Scanty amastigotes may still be found, but they are absent in the necrotic area. Considerable endarteritis may be associated with thrombosis which, together with subsequent fibrosis, deforms and erodes the nasal septum. Liquefaction of cartilage continues, even some distance from the leishmanial nodule and the vascular supply is so reduced that only coarse fibrous tissue can survive.

Blockage of the nasal passages due to the developing lesion usually results in respiratory distress, mouth breathing, and a high frequency of pulmonary infection that may lead to death. Palatal (Figure 4), laryngeal and tracheal lesions are less common; for first-hand accounts of these, reference should be made to Marsden (1986) and Walton (1987).

Differential diagnosis of mucosal leishmaniasis must be made from nasal syphilis (no destruction of the septum), gangosa (ulcerating yaws), blastomycosis, rhinosporidiosis, midline granuloma, carcinoma, and cancrum oris.

Sudanese and Ethiopian oro-nasal (mucosal) leishmaniasis bears a superficial resemblance to American espundia (see El-Hassan et al. 1995, for review). Due largely to *L. (L.) donovani* s.l. and, more rarely, *L. (L.) major*, it is not preceded by a cutaneous lesion. In addition, unlike patients with the South American disease, advanced cases of Sudanese mucosal leishmaniasis respond readily to treatment with pentavalent antimonials and ketoconazole.

Anergic, diffuse cutaneous leishmaniasis

In Venezuela, Convit and Lapenta (1948) described a bizarre form of cutaneous leishmaniasis characterized by nodular lesions scattered all over the body and containing vast numbers of rather large amastigotes; a negative Montenegro skin-test reaction; and almost total resistance to chemotherapy. Further cases were recorded in that country and subsequently in Bolivia, Brazil, Colombia, the Dominican Republic, Honduras, northern Mexico, Texas, USA, and Peru. The causative parasites in Venezuela, Mexico, Texas, and Brazil are *L. (L.) pifanoi*, *L. (L.) mexicana* and *L. (L.) amazonensis* respectively and it is likely that this form of leishmaniasis elsewhere in the Americas is also due to members of the *mexicana* complex within the subgenus *Leishmania*. The disease, as its name suggests, is the outcome of infection by this group of parasites in individuals with little or no cell-mediated immunity. Curiously, parasites of the subgenus *Viannia* do not seem to possess the potential to produce this strange disease.

At one time it appeared that ADCL was an irreversible condition and that the best treatment merely kept the disease in check, without eliminating the parasite. There is some evidence to suggest, however, that the prognosis is not always so grim. One of the several ADCL patients studied in the authors' laboratory acquired her infection with *L. (L.) amazonensis* when she was less than 5 years old and, in spite of constant chemotherapy, her condition had not improved greatly by the age of 28 years. However, the lesions faded away and the patient made a complete recovery following immunochemotherapy. We had noted that, unlike the lesions of other cases of ADCL, those of this young woman had occasionally ulcerated and healed, leaving her with very unsightly scars on her face and legs (Figure 9). This and the final recovery, suggests that there is a gradation in the degree of anergic condition, from total to partial. In many patients, the nodular lesions remain unulcerated, whereas in others, there may be ulceration and even amputation of fingers and toes, resembling that seen in leprosy (Figure 5).

Usually, ADCL forms a minute proportion of the total number of cases of cutaneous leishmaniasis caused by parasites of the *mexicana* complex but an exception is found in the Dominican Republic, where ADCL occurs in the apparent absence of simple, curable cutaneous leishmaniasis. The causative parasite is clearly a member of the *mexicana* complex, but is, as yet, unnamed and its animal reservoir and sandfly vector are unknown. The occurrence of three cases in a single family in the Dominican Republic suggests involvement of an hereditary component (Walton 1987); Petersen et al. (1982) demonstrated a population of specific suppressor cells in four other patients. The deficient immune response in ADCL in general is considered to be related to a thymus-dependent system in both the New World and the Old World diseases (Convit et al. 1971; Bryceson 1970). The only other disease with which ADCL has frequently been confused is lepromatous leprosy; this mistake is unpardonable if Giemsa-stained smears of the skin lesions have been examined (Figure 10).

In a recent paper, Silveira et al. (2004) discussed the clinical and immunopathological spectrum of American

cutaneous leishmaniasis, with particular reference to the disease in Amazonian Brazil. They emphasized the necessity of accurately identifying the species of *Leishmania* stimulating the patient's immune response, together with the quality and magnitude of this response. At the diagramatic center of the authors' clinical spectrum are the most commonly seen localized forms of cutaneous leishmaniasis (LCL), which may be caused by members of both subgenera, *Leishmania* and *Viannia*, and which usually respond well to conventional chemotherapy. The two pathogenicity poles of the spectrum generally recognized are the hyposensitivity pole, occupied by cases of ADCL, and the hypersensitivity pole represented by mucocutaneous leishmaniasis. They proposed the term borderline disseminated cutaneous leishmaniasis (BDCL) for the cases showing disseminated lesions due to some parasites of both the subgenera where there is a partial failure of the cellular immune response (unlike the complete failure seen in ADCL), enabling eventual cure of the patient provided that treatment is promptly given. If this is not undertaken, however, these infections may develop into either ADCL (due, for example, to *L. (L.) amazonensis*) or mucocutaneous leishmaniasis (due mainly to *L. (V.) braziliensis*).

Leishmania infections and the immunosuppressed patient

Cutaneous and visceral leishmaniasis are now firmly established in the list of infections that the clinician must consider when dealing with immunosuppressed patients, in particular those with acquired immune deficiency syndrome (AIDS). Visceral leishmaniasis is the clinical form most commonly associated with HIV/AIDS and has become a public health problem of considerable proportions in south-western Europe. Strangely, although visceral leishmaniasis is far more common in many parts of Latin America (e.g. Brazil) than it is in Europe, cases of AVL/HIV infection are, until now, less common (WHO 1998). Possibly this is because, in the Americas, HIV is predominantly found in the larger cities; the situation will doubtless change as HIV spreads to the more rural areas where AVL is highly endemic or with the migration of leishmaniasis carriers into the large cities and their acquisition of HIV. One of the most striking examples of such migration is that of individuals from the rural areas of northeast Brazil, where AVL is very common, into São Paulo city in search of work. Co-infection of HIV and *Leishmania* species responsible for cutaneous leishmaniasis seems to be less frequent in the Americas, but may result in serious complications, ranging from disseminated skin lesions and mucosal lesions (Coura et al. 1987; Da-Cruz et al. 1999) to rectal involvement (Hernández et al. 1995). *L. (V.) guyanensis* has been isolated from the lesions of an HIV patient presenting with mucocutaneous leishmaniasis in the State of Amazonas, Brazil (de Souza e Souza et al. 1998), and visceral leishmaniasis due to *L. (L.) mexicana* has been recorded in a patient with HIV in Mexico (Ramos-Santos et al. 2000).

PREVENTION AND CONTROL

Visceral leishmaniasis

Campaigns are of fundamental importance, with the distribution of illustrated pamphlets to alert the populations as to the early symptoms of the disease, the signs of infection in the dog and the appearance and habits of the sandfly vector. The staff of small, rural clinics must be trained to recognize visceral leishmaniasis and should have means of reporting suspected cases to centers where more conclusive diagnosis can be made. In view of the impecunious situation of many inhabitants of the rural districts of developing countries, the staff of such centers may need to travel to the patient's village, where the possibility of other cases must be investigated. Periodic surveillance of populations at risk may detect cases of early infection either clinically or, more effectively, by serological methods that can easily be carried out under field conditions, such as the direct agglutination test (DAT) or the dot-ELISA.

In areas of high endemicity, such as the states of Ceará and Bahia in northeast Brazil, past control measures (i.e. destroying infected dogs, regular insecticide spraying of houses and animal sheds, and the early treatment of patients) resulted in a dramatic drop in the number of cases of AVL. A problem arises, however, in maintaining such a control program, which is costly and inevitably meets with considerable opposition on the part of dog owners, who fail to understand why their apparently healthy (but serologically positive) animals must be killed. Many deliberately conceal their dogs, and many strays are never examined. A critical evaluation of the cost-effectiveness of this dog-slaughtering policy (Akhavan 1996) points out the vast amount of work and expense expended in surveying dog populations, and the apparent failure of this method in control programs in some parts of Brazil has led to the question as to what extent the dog population needs to be reduced in order to eliminate AVL or to bring it under control. It has been suggested that it may be preferable to find improved methods of eliminating or controlling the sandfly vector.

Insecticide (deltamethrin)-impregnated plastic dog collars have been found to provide an efficient and prolonged protection of dogs against the bites of sandfly vectors of *L. i. infantum*, thus breaking transmission of the parasite in its major reservoir host (Killick-Kendrick et al. 1997). Such collars have been shown to offer similar protection against the bites of *Lu. longipalpis* in Brazil (David et al. 2001), and preliminary results

following field-trials in three regions of Brazil have been discussed in the 2002 *Proceedings of the Second International Cannine Leishmaniasis Forum, Seville, Spain*. Only after the completion of more lengthy field-trials, however, will it be possible to assess both the cost-efficiency of deltamethrin-impregnated dog collars, or other methods of insecticide application, and the effects they may have on the incidence of human AVL. In the meantime, the development and use of an effective and long-lasting vaccine, preferably in a well-supervised, governmental program similar to that of antirabies campaigns, remains of great importance. Encouraging results have been obtained after the inoculation of dogs with a mixture of promastigotes of *L. (V.) braziliensis*, disrupted by ultrasound, and bacille Camette Guerin (BCG). Of 10 vaccinated dogs, only one succumbed to subsequent challenge with 2.3×10^6 infective promastigotes of *L. i. chagasi*, whereas all of nine nonvaccinated dogs became infected (Mayrink et al. 1996). In addition, field trials using a fucose–mannose ligand (FML)-vaccine prepared from *L. donovani* have afforded a 92 percent protection among dogs in an endemic area of AVL in Rio Grande do Norte, Brazil, 2 years after their vaccination. The 8 percent of dogs that did acquire infection showed only mild signs of disease with no deaths and, significantly, the number of human cases of AVL in the area decreased from 15 in 1996 to six in 1997 and none in 1998 (da Silva et al. 2001).

Cutaneous and mucosal leishmaniasis

Most inhabitants of the endemic areas are very familiar with the dermal leishmaniases, under their wide variety of local names, but ignorance and negligence are all too frequently to blame for allowing these diseases to reach debilitating or mutilating proportions. The painless nature of the lesions makes them of no great inconvenience in their early stages and this encourages the tendency to wait and see if they will cure spontaneously. Again, as these diseases are predominantly zoonotic, most infections are acquired by those living in rural areas, often long distances from the simplest of medical attention. As a result, a high proportion of cases only seek help when the infection is well advanced and, in regions where the causal agent is frequently *L. (V.) braziliensis*, this may prove disastrous. As for visceral leishmaniasis, health education campaigns can help to indicate the importance of early treatment.

Personal avoidance of cutaneous leishmaniasis is, at present, limited to the use of insect repellents, protective clothing and the avoidance of danger areas, particularly at night when the sandfly vectors are most active. These are precautions that may be feasible for the visiting tourist, but they are not very practical for the shirtless forest-worker who can ill afford to be constantly purchasing insect repellents, who is most comfortable wearing shorts (far less expensive than trousers) and short-sleeved shirts and who has to eke out his living by hunting in the forest at night.

The prevention or control of sylvatic leishmaniasis among gangs of laborers, topographers, and other forestry workers can be effective on a small scale by the following measures: placing the encampments of such men in adequate clearings; spraying the bases of the larger, nearby tree trunks with insecticides (e.g. in areas where the vectors are known to be arboreal – see *Leishmania* (*Viannia*) *guyanensis* Floch, 1954 above); and prohibiting night-time hunting. Destruction of the wild animal reservoirs of sylvatic leishmaniasis is clearly neither practical nor desirable. Finally, knowledge of the ecology of a vector can sometimes help in preventing acquisition of the disease under certain circumstances. Thus, *Psychodopygus wellcomei*, an important vector of *L. (V.) braziliensis* s.l. in the highland forests of Pará, north Brazil, is highly anthropophilic and attacks humans not only at night but also frequently during the day. Field studies have shown, however, that this sandfly is only active for about 6 months of the year, during the rainy season (November–April) and that it enters into diapause in the dry season during the rest of the year, when adult flies are rarely seen. The area in question is one of intense human activity due to the mining of iron ore and other minerals and the incidence of cutaneous leishmaniasis has been very high among those clearing the primary forest. Planning such work for the dry season clearly avoids contact with the sandfly vector.

Although drastic ecological changes such as deforestation and the planting of non-indigenous pine, gmelina, and eucalyptus trees might lead to unfavorable conditions for the enzootics of some species of *Leishmania*, it can actually encourage others. Thus, the creation of vast monoculture plantations of non-indigenous trees for paper pulp production in north Brazil may eliminate cutaneous leishmaniasis due to *L. (V.) guyanensis* in the immediate areas, as neither the major reservoir host (the two-toed sloth) nor the sandfly vector (*Lu. umbratilis*) find this new environment suitable. On the other hand, the wild rodent and marsupial hosts of *L. (L.) amazonensis* and the sandfly vector, *Lu. flaviscutellata*, find it ideal.

In those parts of Latin America where vector species have adapted to a peridomestic or domiciliary habitat, the use of insecticides is clearly indicated. In the absence of firm evidence that domestic animals with leishmanial skin lesions offer a source of infection to sandflies, it would seem unwise to recommend their destruction, even in the unlikely event of their owners' consent. Equines respond well to antimonial treatment.

Direct transmission risks

Cases of congenital transmission of visceral leishmaniasis have been reported (Bialek and Knobloch 1999; Knobloch et al. 2001) but would appear to be rare.

It has been estimated that in some endemic areas infection with leishmanial parasites may be as high as 70 percent of the population, and data on patients with *Leishmania*/HIV co-infection have indicated that viable parasites may persist in individuals long after initial infection, irrespective of the presence or absence of primary disease (WHO 1998). Leishmanial antibodies have been detected in 9 percent of a group of blood donors in the city of Natal, Rio Grande do Norte, Brazil, and in 37 percent of patients undergoing hemodialysis in the same locality (Luz et al. 1997); the latter figure was significantly higher than in any other group, including inhabitants in AVL foci on the outskirts of the city! The importance of transfusion transmission of visceral leishmaniasis in Europe has been clearly indicated in non-endemic regions where the sandfly vector is absent (Mauny et al. 1993). With increases in HIV infection and organ transplant surgery involving prolonged use of immunosuppressants, occult infections and contaminated blood or organs become life-threatening risks necessitating special precautions (Schulman 1994).

TREATMENT

Of the various drugs discussed for the treatment of leishmaniasis (see Old World leishmaniasis; Lainson 1982a; Amato et al. 1996; de Carvalho et al. 2000), the pentavalent antimonials are those of first choice in dealing with the neotropical leishmaniases. It is of historical interest that the first use of antimony to treat leishmaniasis was in Brazil. A young clinician, Gaspar Vianna, impressed by the effectiveness of tartar emetic (antimony potassium tartrate) in the treatment of African trypanosomiasis (see African trypanosomiasis), realized its potential against the related organism *Leishmania* and, in 1912, published his spectacular results obtained with this drug in advanced cases of mucocutaneous leishmaniasis (Vianna 1912). There followed development of the somewhat less toxic trivalent antimonials, which still produced unpleasant side-effects, and then the much better-tolerated pentavalent antimonials which, some five decades later, are still the clinician's principal armaments. Even so, these latter, more refined antimonials may sometimes show some cardiotoxicity (Ribeiro et al. 1999).

American visceral leishmaniasis

Treatment usually follows that given in Old world leishmaniasis. Unresponsiveness to the recommended antimonial dosage schedule, however, has been noted in some AVL patients from Bahia, Brazil. In such cases, there is little alternative other than elevating the dosage or using second-line drugs such as pentamidine. In this manner, Bryceson et al. (1985) cured four of ten unresponsive patients with Kenyan kala azar, but all ten suffered serious side-effects from both stibogluconate and pentamidine at the dosage levels used. Liposomal amphotericin B (AmBisome®) is recommended for the treatment of visceral leishmaniasis by the US Food and Drug Administration (Meyerhoff 1999).

Cutaneous leishmaniasis

Once again, the treatment is much the same as that for Old World cutaneous leishmaniasis, using the pentavalent antimonials. Many clinicians prefer, however, to use the intravenous route for both pentostam and Glucantime, rather than intramuscular inoculation.

In general, lesions due to the neotropical leishmanias tend to much greater chronicity than those of the Old World and there is not such a ready response to treatment. There is no justification in delaying treatment in anticipation of an early spontaneous cure, as recommended with *L. (L.) major* or *L. (L.) tropica* infections, or limiting treatment to intralesional injection of drugs or the topical application of these in ointments. The following hazards must be considered: subsequent mucosal disease due to *L. (V.) braziliensis*; ADCL due to parasites of the *mexicana* complex; and multiple lesions following lymphatic or hematogenous spread on the part of *L. (V.) guyanensis*. Treatment should, therefore, be systemic and immediate and identification of the causative parasite is most important. If it proves to be *L. (V.) braziliensis*, treatment should be particularly intensive.

Effectiveness of the pentavalents Pentostam® and Glucantime may vary considerably, not only when dealing with different parasites, but in treating different patients infected with the same organism. Some patients with simple lesions due to *L. (V.) guyanensis*, for example, may be cured by a single course of treatment, whereas others may require three or four. In some cases of poor response, recourse must be made to other drugs, or combinations of drugs, in spite of their greater toxicity. The most commonly used second-line drug is pentamidine, which has been used routinely by French workers in treating cases due to *L. (V.) guyanensis* in French Guyana.

Treatment of patients with the antimalarial drug mefloquine has produced conflicting results (Gómez et al. 1996; Hendrickx et al. 1998; Laguna-Torres et al. 1999).

Mucocutaneous and mucosal leishmaniasis

Advanced cases are difficult to treat, with slow response to the pentavalent antimonials. The high dosage recommended (20 mg Sb^{5+} per kg body weight, given in a single daily injection for a mean of 30 days, or until no evidence of activity of the lesion has been noted for a week) may sometimes produce pronounced side-effects, so that treatment has to be suspended (Marsden 1986).

The considerably more toxic amphotericin B and pentamidine are used only when there is failure to respond to the pentavalent antimonials. In some patients, the early treatment provokes a severe inflammation around the lesion, presumed to be caused by antigen released from killed parasites. Although this reaction is regarded as a favorable prognostic sign, it may prove highly dangerous in patients with laryngeal or tracheal lesions. It is recommended that corticosteroids be used as a prophylactic measure when treating such cases and that there should be a gradual elevation of the drug dose (Marsden 1986). Successful treatment of mucosal leishmaniasis in patients unresponsive to Glucantime has been achieved with liposomal amphotericin B (Sampaio and Marsden 1997).

Another difficulty confronting the clinician is in evaluating the effectiveness of treatment. What are the criteria of cure? Serological monitoring has used complement fixation and indirect fluorescent antibody tests, and it has been suggested that cure is indicated by decline and disappearance of antibody titers (Walton 1987). This method is likely to prove the most useful, provided that measurements of leishmanial antibody can be standardized. Both parasitological and histological examination entail biopsy trauma to the treated lesion and may reactivate a lesion that seems to be healed but still contains parasites. Serological follow-up should accompany testing for antigen: a negative antigen test together with reduced titer in serological tests indicates a lower likelihood of relapse (Amato et al. 1998), but an inflammatory process may persist, even in these patients, and could indicate continued presence of amastigotes.

Mutilation following the mucosal lesions may be so extreme that even after cure the patient is ostracized and unable to lead a normal life. Plastic surgery is helpful, but only when there is no doubt of cure. Walton (1987) cites the case of one patient, with apparently complete healing, who underwent cosmetic surgery to reconstruct his nose: 'The results were disastrous, with widespread reactivation along the surgical wounds and, in the patient's words – the new nose fell off!'.

Immunotherapy, utilizing vaccines with or without BCG (Convit et al. 1987, 1989; Mayrink et al. 1991) has proved effective, but has been shown to give much the same cure rate as conventional chemotherapy (Convit et al. 1987). As pointed out by the latter authors, however, it is considerably cheaper and safer.

Anergic diffuse cutaneous leishmaniasis

A smooth, fleshy, unulcerated lesion containing very abundant, large amastigotes in a patient with a negative Montenegro skin-test reaction is a danger signal that should prompt immediate, high-dosage antimonial treatment. In the authors' laboratory in Amazonian Brazil, this is virtually diagnostic of an early lesion due to *L. (L.) amazonensis* which, in an individual with a defective cell-mediated immune response (suggested by his negative skin-test), will proceed to ADCL unless adequately treated. Fortunately, although simple, curable skin lesions due to this parasite are quite common, ADCL is relatively rare.

Of all the forms of leishmaniasis, this disease undoubtedly represents the clinician's greatest challenge, because the patient is unable to offer the all-important immunological collaboration necessary for successful drug treatment. Advanced cases of ADCL, with multiple nodular lesions, may respond dramatically to the first antimonial treatment, with complete disappearance of the lesions. Unfortunately, this may be taken to indicate cure, but with the cessation of treatment the nodules reappear some time later, usually more abundantly. Repeated treatment with the same drug may again give good results, but the patient will relapse again and the response steadily diminishes until the treatment is virtually ineffective. Similar results may be obtained with a variety of other drugs, until the list is exhausted and the patient's situation becomes desperate.

In patients with ADCL due to *L. (L.) amazonensis*, very hot baths taken daily, together with periodic chemotherapy, have been found to reduce the size of the nodules substantially, giving the patient a much improved appearance over periods of many years (Lainson 1982a). More recently, immunochemotherapy has been used with considerable success in the treatment of persons suffering from ADCL in Venezuela (Convit et al. 1989). 'Marked clinical improvement' was observed in nine out of ten patients given intradermal injections of a mixture of heat-killed promastigotes of '*L. mexicana amazonensis*' (*L. (L.) pifanoi*?) isolated from a Venezuelan case of ADCL, plus 'variable amounts' of BCG, together with the standard Glucantime treatment. A similar treatment of Brazilian ADCL patients infected with *L. (L.) amazonensis*, however, has met with limited success (F.T. Silveira, unpublished observations). Treatment with an association of Glucantime and paramomycin (Gabbrox, via oral) has been found useful (Costa et al. 1999).

VACCINATION

Immunology of infectious diseases in general is discussed in Immunology and immunopathology of human parasitic infections. With regards to leishmaniasis, this is just as well, because a detailed review of the extensive literature on this subject over the past few years would fill many more pages here than space allows.

The pioneer work of Mayrink and collaborators in Brazil, on the production of a vaccine against American cutaneous and mucocutaneous leishmaniasis (reviewed by Genaro et al. 1996), and that of Convit and coworkers in Venezuela on the use of vaccines in immu-

notherapy (reviewed by Convit 1996) have triggered a veritable explosion of studies directed towards the production of vaccines

In early trials, the Mayrink vaccine was a mixture of killed, sonicated promastigotes of *L. (L.) amazonensis*, *L. (V.) braziliensis*, and a *Leishmania* of doubtful identity, without the use of an adjuvant. More recent versions have been a cocktail of promastigotes of *L. (L.) mexicana*, *L. (L.) amazonensis*, *L. (V.) guyanensis*, and *L. (V.) braziliensis*, with or without *Corynebacterium parvum* as an adjuvant. While apparently still some way from offering complete protection, the vaccine at least has the distinction of being the only one commercially available (Leishvacin®), and it is to be hoped that continuing studies will improve its efficacy. The protective efficacy of a similar vaccine against cutaneous leishmaniasis in Ecuador is claimed to be 72.9 percent (Armijos et al. 1998).

The immune response of volunteers vaccinated with BCG plus killed promastigotes of *L. (L.) mexicana* in Venezuela indicated the vaccine to be potentially protective for the majority of the vaccinees (Sharples et al. 1994), and follow-up studies showed an immune response in more than 85 percent of the vaccines as indicated either by skin-test conversion, lymphocyte proliferation or interferon-γ production.

Kenney et al. (1999) used rhesus monkeys to assess the safety, immunogenicity, and efficacy of a vaccine prepared from heat-killed *L. (L.) amazonensis* promastigotes combined with recombinant human interleukin-12 (rhIL-12) and aluminum hydroxide gel as adjuvants. Challenge with 10^7 metacyclic *L. (L.) amazonensis* promastigotes 4 weeks after vaccination demonstrated complete protection in 12 monkeys that received 2 μg rhIL-12 with alum/antigen. The safety and efficacy of this vaccine in monkeys suggest a basis for human trials.

Handman (2001) gives a useful update of work on killed and live, attenuated vaccines; recombinant vaccines; synthetic peptides; nonprotein antigens; and 'naked' DNA vaccine. Transmission-blocking vaccines are discussed by Tonui (1999).

CONCLUDING REMARKS

We have discussed the possible origin of the parasitic Kinetoplastida, the family Trypanosomatidae, and the genus *Leishmania* elsewhere (Lainson and Shaw 1987). It is the general opinion that the trypanosomatids have their origin in monogenetic intestinal flagellates of invertebrates and that they subsequently adapted to spend a part of their life-cycle in vertebrates. Thus, it is more correct to consider the phlebotomine sandfly as the primary host of *Leishmania* species, rather than the vertebrate hosts that merely function as reservoirs of infection for the sandfly (Lainson 1997). The finding that promastigotes may undergo a form of conjugation (Lanotte and Rioux 1990), with possible exchange of nuclear material, supports this hypothesis on the reasonable assumption that such a process is more likely to take place in the definitive or primary host of a heteroxenous parasite.

It is difficult to assess the specificity of the *Leishmania* species in their sandfly hosts and unwise to base one's conclusions on the results of laboratory experiments, when unnaturally large numbers of amastigotes or promastigotes, fed to laboratory-bred flies, may well overwhelm the natural resistance of a nonvector species. In nature, however, there is considerable evidence suggesting the limitation of the life-cycle of most leishmanial parasites to specific sandfly vectors. Thus, *Lu. longipalpis* is the major vector of *L. (L.) chagasi* throughout the whole geographical range of this parasite; the closely related *Lu. olmeca olmeca* and *Lu. flaviscutellata* are the only confirmed vectors of *L. (L.) mexicana* and *L. (L.) amazonensis* respectively, in Central and South America, in spite of the presence of many other species of sandflies known to feed on rodents in the endemic areas of these two parasites. As far as is known, *Ps. wellcomei* is the sole vector of *L. (V.) braziliensis* s.l. in the Carajás highlands of Pará and *Lu. umbratilis* is the major vector of *L. (V.) guyanensis* throughout its geographical distribution, again in spite of the presence of a large number of other species of sandflies. On the other hand, because some sandfly vectors feed on a variety of mammalian hosts in nature, the *Leishmania* of a given species of sandfly may sometimes be isolated from a variety of mammalian hosts sharing the same habitat. *Lu. flaviscutellata,* for example, is a low-flying sandfly and transmits *L. (L.) amazonensis* to a number of predominantly terrestrial rodents and marsupials; canopy and tree trunk-dwelling sandflies such as *Lu. umbratilis* and *Lu. whitmani* s.l. transmit *L. (V.) guyanensis* and *L. (V.) shawi*, respectively, to arboreal animals such as sloths, anteaters, monkeys, and procyonids.

The number of *Leishmania* species in a given locality will largely be governed by the number of sandfly species, although some sandflies seem to be resistant to infection with this parasite. Thus, we (Lainson and Shaw, unpublished observations) have failed to infect the sandfly *Lu. carmelinoi* with any neotropical *Leishmania* species. The multiplicity of species within the genus is a relatively recent realization and much research is still needed to further our knowledge regarding the diversity, ecology, and taxonomy of the neotropical leishmanias. For the clinician, the continued isolation and characterization of parasites from cases of human leishmaniasis is sufficient to indicate the spectrum of *Leishmania* species commonly infecting humans in a given area. The parasitologist's interests, however, are much wider and include the wild mammalian reservoir and sandfly vectors of those parasites infecting humans, as well as the possible existence of other *Leishmania* species that rarely, if ever, infect humans.

The number of *Leishmania* species in the neotropical region is anybody's guess and some idea of it will only be gained when sufficient numbers of mammalian and sandfly species have been examined. Clearly, it is easier and more economical to concentrate simply on the sandfly population, a truly gigantic task in itself considering that nearly 400 different species of these insects have been identified in the Americas (Young and Duncan 1994). The Amazon Region has already provided us with almost half of the recognized species of neotropical leishmanias and doubtless this great forest will continue to provide us with many more!

ACKNOWLEDGMENTS

The authors are indebted to the Wellcome Trust, London, for the financial support of our studies on the ecology, epidemiology, and taxonomy of *Leishmania* in the Amazon Region of Brazil over the past 30 years and to the Instituto Evandro Chagas, Belém, Pará, where this work was carried out.

INTRODUCTION

African trypanosomiasis, or sleeping sickness, is a human disease caused by *Trypanosoma brucei rhodesiense* and *T. b. gambiense* that inhabit the fluid compartments of blood, lymph, and interstitial fluids of their human hosts (Figure 1). The parasites belong to:

Kingdom Protozoa
Phylum Euglenozoa
Class Kinetoplastea
Order Trypanosomatida
Genus *Trypanosoma* Gruby, 1843
Section *Salivaria*
Subgenus *Trypanozoon*
Species *Trypanosoma brucei*

This pedigree, distilled from more than one and a half centuries of observation by systematists, signifies that in addition to causing sleeping sickness in people, the parasites are single-celled eukaryotes with a single flagellum, no chloroplast, a conspicuous aggregate of DNA located near the flagellar kinetosomes in a single mitochondrion, and that they are transmitted from the anterior station, i.e. the proboscis, of tsetse flies.

Sleeping sickness is endemic to sub-Saharan Africa and arises within the habitat of tsetse flies (Genus *Glossina*, Order Diptera), which are the primary vectors of African trypanosomes and in which trypanosomes undergo cyclic development. Tsetse flies are constrained by temperature and humidity boundaries that are met within vast swaths of the humid and semi-humid zones of Africa. They infest a land mass of about 10 million square kilometers ranging from the southern boundary

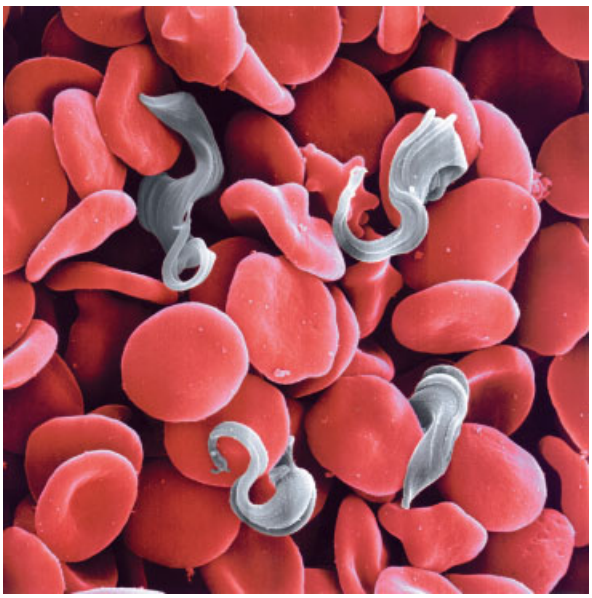

Figure 1 Trypanosoma brucei *in a typical habitat within a mammal. The parasites inhabit the extracellular compartment of blood and tissue fluids and are shown here among red blood cells in a smear of infected blood. (Courtesy of Jürgen Berger and Dr Peter Overath, Max Planck Institute for Developmental Biology, Tübingen)*

of the Saharan desert to around 20° south of the Equator. Within this region, the *Morsitans* subgenus inhabits the savanna, the *Palpalis* subgenus inhabits riverine valleys, the *Austeni* subgenus inhabits thickets, and the *Fusca* subgenus inhabits the forests. All subgenera of *Glossina* transmit African trypanosomes but *T. b. gambiense* is mainly transmitted by the *Palpalis* subgenus and *T. b. rhodesiense* by the *Morsitans* subgenus.

Some species of trypanosomes (see below) infect cattle and other domesticated animals causing a wasting disease, nagana, which costs producers about US$3 billion each year in lost productivity. Some environmentalists see nagana as a disease barrier that protects Central Africa from becoming home to monocultures of grassland and cattle. To others, it is a garrote strangling the capacity of sedentary agriculturists in Central Africa to establish profitable integrated agricultural systems. Both points of view have merit. Overgrazing and environmental degradation are prevalent in some grazed regions abutting the Sahara and could spread south if nagana was no longer a problem. On the other hand, the inability to keep cattle in Central Africa because of trypanosomiasis prevents that region from following successful models of agrarian development established elsewhere.

The importance of trypanosomiasis to human and livestock health in Africa was recognized early in the period of European colonial expansion in Africa (Ford 1971). Various historical accounts of the early work on the epidemiology, the control measures, and the social and economic consequences of trypanosomiasis are available (Duggan 1970; Ford 1971). By the late-1950s, human trypanosomiasis had been contained through vector control, vector avoidance, and a combination of diagnosis and treatment through chemotherapy. Despite this early success, the disease is now a serious public health problem in much of sub-Saharan Africa. The breakdown of public health programs and, as a consequence, a reduction of disease surveillance and treatment, appear to be key factors in disease resurgence. The incidence of sleeping sickness has now reached epidemic proportions in Angola and the Democratic Republic of Congo (formerly the Republic of Zaire) and is high and increasing in Uganda and Sudan. Only about 10 percent of people at risk are screened for trypanosomiasis and of these only a small proportion are treated. It is estimated that 300 000–500 000 people have sleeping sickness, and in some areas the incidence of disease exceeds that of acquired immune deficiency syndrome (AIDS). The incidence of trypanosomiasis is unlikely to decline in the near future unless aggressive diagnosis and treatment regimes are re-established and efforts made to reduce the prevalence of tsetse flies and to limit their contact with people. The World Health Organization is working to achieve these goals by re-enacting earlier successful control programs. These include:

- the assembly of mobile medical teams equipped with the latest diagnostic capability and treatment drugs
- survey of the population at risk with subsequent provision of chemotherapy
- establishment of local health centers to provide long-term care and post-therapy follow up
- motivation of rural communities to assume responsibility for vector control programs and health care initiatives.

This is all timely but vulnerable to unstable sociopolitical conditions. Unfortunately, there are no alternatives: neither long-lived chemoprophylactic treatments nor effective vaccines have been developed.

CLASSIFICATION

There are several species of African trypanosomes distributed through four subgenera: subgenus *Duttonella* (*D*), *Nannomonas* (*N*), *Trypanozoon* (*T*) and *Pycnomonas* (*P*).

Order Trypanosomatida
  Family Trypanosomatidae
    Genus *Trypanosoma*
    Section Stercoraria
    Subgenus *Schizotrypanum*
      Species *T.* (*S*) *cruzi*
    Section Salivaria
    Subgenus *Duttonella*
      Species *T.* (*D*) *vivax*
    Subgenus *Nannomonas*
      Species *T.* (*N*) *congolense*
      Species *T.* (*N*) *simiae*
    Subgenus *Trypanozoon*
      Species *T.* (*T*) *brucei*
      Subspecies *T.* (*T*) *b. brucei*
      Subspecies *T.* (*T*) *b. rhodesiense*
      Subspecies *T.* (*T*) *b. gambiense*
      Subspecies *T.* (*T*) *equiperdum*
      Subspecies *T.* (*T*) *evansi*
    Subgenus *Pycnomonas*
      Species *T.* (*P*) *suis*

The subgenera and species are distinguished on morphologic, isoenzyme, molecular diagnostic, and host-specificity criteria. The sub-genus *Trypanozoon* contains the human infective trypanosomes and is considered to be 'in the midst of a period of rapid evolution at the present time, which makes it difficult for systematists to divide it up neatly into distinct species' (Kreier and Baker 1987). There are two groups of *Trypanozoon* organisms. The first, referred to as the *T.* (*T*) *brucei* group, includes the human infective pathogens *T. b. gambiense* and *T. b. rhodesiense*, and a morphologically identical subspecies, *T. b. brucei*, that does not infect humans. All members of the *T.* (*T*) *brucei* group are transmitted by tsetse flies. Their taxonomic relationships are further discussed below based on molecular characterization and sensitivity to human serum. Kreier and

Baker (1987) use the term *T. brucei* s.l. (= sensu lato, in the broad sense) to describe the *T.* (*T*) *brucei* group. This usage is awkward and in the rest of this chapter when we refer to *T. brucei* without any further qualification it should be taken to mean *T. brucei* s.l.

The second group of *Trypanozoon* species is comprised of *T. evansi* and *T. equiperdum*. These parasites are not cyclically transmitted by tsetse flies. Their taxonomic relationship with each other and with their putative parent species *T. brucei* is unclear. It is thought that they evolved from *T. brucei* organisms that had been carried beyond the northern boundary of the tsetse habitat by infected camels and subsequently 'adapted to noncyclical transmission by biting Diptera and so survived and underwent speciation on their own' (Kreier and Baker 1987). *T. evansi* is widely spread through North Africa, Asia, and South America. Camels, cattle, water buffalo, horses, and dogs are common hosts. *T. equiperdum*, a parasite of horses and donkeys, is morphologically identical to *T. evansi*. It is not dependent on an invertebrate vector but accumulates in inflammatory sites on the skin, including the genitalia that are abraded during coitus thus permitting transfer of the parasites to uninfected breeding partners.

Trypanosoma b. brucei, which is morphologically indistinguishable from the human-infective *T. brucei* subspecies, does not infect humans but does infect cattle and, together with *T.* (*D*) *vivax* and *T.* (*N*) *congolense*, causes nagana, a fatal disease of these livestock. *T. b. brucei*, *T. congolense*, and *T. vivax* are widely distributed throughout the tsetse fly habitat and their presence excludes cattle from all but the fringes of it.

The *T.* (*T*) *brucei* complex and human infectivity

Members of the *T.* (*T*) *brucei* complex, *T. b. brucei*, *T. b. rhodesiense*, and *T. b. gambiense*, share phenotypic characteristics including their morphology, life cycle, and major biochemical features. However, there is significant intraspecific variation evidenced by differences in isoenzyme electrophoretic patterns and in restriction fragment length polymorphisms (RFLP). Cluster analysis of data on isoenzyme variation show that the African trypanosomes can be placed into a number of different principal zymodeme groups. *T. b. gambiense* trypanosomes are fairly homogenous by zymodeme analysis and can be distinguished by this method from *T. b. rhodesiense* and *T. b. brucei* (Stevens and Godfrey 1992). *T. b. gambiense*, *T. b. rhodesiense*, and *T. b. brucei* can be distinguished on the basis of RFLP fingerprints (Hide et al. 1994, Agbo et al. 2002) but intra-subspecies variability exists reducing the usefulness of this test. Evaluation of *Trypanozoon* organisms using a repeated coding sequence and microsatellite markers (Biteau et al. 2000) has revealed great heterogeneity in genotype related to these sequences; however, group-specific genotypes, or alleles, were evident and a *T. b. gambiense* group could be distinguished on the basis of their pattern of reactivity with the probes. Many workers have concluded that the African trypanosomes are evolving rapidly with respect to their population genetics and epidemiology, accounting for the complex variations in isoenzyme and RFLP patterns found among various isolates from tsetse, different host groups, and distinct geographical locations.

T. b. gambiense and *T. b. rhodesiense*, but no other African trypanosomes, are infective for humans. Infections initiated with *T. b. rhodesiense* are more acute than those initiated with *T. b. gambiense* although both are fatal if left untreated. *T. b. rhodesiense* and *T. b. gambiense* also have differing geographic distributions: the former are prevalent in the Eastern half of the African continent within the tsetse habitat, and the latter are prevalent in West and Central Africa. The two groups meet and overlap around the Northern and Eastern shores of Lake Tanganyika.

T. b. gambiense and *T. b. rhodesiense* can be incubated in human serum with no ill effects. In contrast, *T. b. brucei* is lysed by incubation in human serum and is not infective to humans. *T. vivax* and *T. congolense*, which also are not infective for humans, are similarly lysed when incubated in human serum (Black et al. 2001) and it is likely that the other trypanosome species that do not infect humans will be equally sensitive. Lysis in human serum provides a simple, although only partly reliable, method of distinguishing *T. b. brucei* from the human infective *T. brucei* subspecies (Rickman and Robson 1970; Robson and Rickman 1978). The test can record false negatives because human-infective *T. brucei* can reversibly give rise to forms sensitive to human serum when freed from the selective pressure of human serum. Furthermore, individual human serum samples vary with respect to their lytic activity on sensitive *T. brucei* subspecies and a given sample can have higher activity against one or another isolate.

Two species of trypanolytic material have been isolated from human serum, a very high density lipoprotein (VHDL) subfraction containing apoliproteins A-I, A-II, C-I, C-II, C-III, haptoglobin-related protein (hpr), and paraoxonase-arylesterase (Smith et al. 1995), and a non-lipoprotein component that contains apo AI, hpr, and IgM (Raper et al. 1999). *T. b. brucei* that are incubated with human serum undergo characteristic changes in their morphology, starting with pronounced swelling around the flagellar pocket region. It is considered that uptake of the lytic material results in disruption of an endocytic and most likely a lysosomal compartment. The hpr component of the trypanolytic factors has been proposed as the targeting device, allowing the lytic complexes to bind to, and be endocytosed by, the parasites. However, hpr alone, or in combination with mouse serum components, does not harm the parasites (Hatada

et al. 2002). In a stunning series of experiments, Pays and his group have now shown that apolipoprotein L-1 is the lytic factor in human serum and that this minor component of high density lipoprotein exerts its effect in the presence or absence of hpr (Vanhamme et al. 2003). The apolipoprotein L-1 is endocytosed by the parasites and processed in a lysosome. The mechanism through which endocytosed apolipoprotein L-1 destabilizes the *T. b. brucei* lysosomal membrane has not been resolved.

T. b. rhodesiense express a human serum resistance associated (SRA) gene (De Greef et al. 1989), which, upon transfection into *T. b. brucei*, confers resistance to lysis by human serum (Xong et al. 1998) and which can be used as a molecular confirmation of *T. b. rhodesiense* (Welburn et al. 2001; Gibson 2001a). SRA has been shown by Pays and colleagues (Vanhamme et al. 2003) to encode a lysosomal protein that most likely confers resistance to the lytic activity of apolipoprotein L-1 by reacting with the protein in the lysosome. Unlike *T. b. rhodesiense*, *T. b. gambiense* do not express SRA and the mechanism used by these parasites to resist lysis in human serum has not been resolved. Although many crucial details remain to be resolved as to how human serum lyses *T. b. brucei* and how this process is prevented in other *T. brucei* subspecies, the basic finding that apolipoprotein L-1 is the lytic factor of human serum is of huge significance. This finding may lead to novel transgenic solutions to nagana as well as to the development of therapeutic peptides for *T. b. rhodesiense*-sleeping sickness.

STRUCTURE AND LIFE CYCLE

Kinetoplast

Trypanosoma brucei are spindle shaped protozoa about 20 μm in length and 1–2 μm in width. The parasites have the common features of eukaryotic cells, namely a lipid bilayer plasma membrane that encloses a number of membrane-bound organelles including the nucleus, mitochondria, Golgi apparatus, endoplasmic reticulum, and endosomal vesicles (Figure 2). They have a single flagellum that emerges from an invagination in the plasma membrane called the flagellar pocket. African trypanosomes also have a number of special organelles. The most notable of these is a mass of mitochondrial DNA called the kinetoplast from which the Class Kinetoplastea gains its name and, as a consequence, the group as a whole is frequently referred to as kinetoplastid flagellates. The kinetoplast is a network of DNA arranged as a flask-shaped body. It is located within the organism's single mitochondrion at the posterior end of the parasite, close to its flagellar pocket. The kinetoplast is composed of a few identical maxicircles each of 20–40 kb intertwined with thousands of minicircles of 0.5–3 kb. The interlinked nature of maxicircle and minicircle DNA in the kinetoplast presents unique problems with respect to replication of this body and has been the subject of extensive investigation (reviewed in Morris et al. 2001). The kinetoplast maxicircles house mitochondrial genes, some of which require extensive editing at the mRNA level (discussed later) to yield functional proteins.

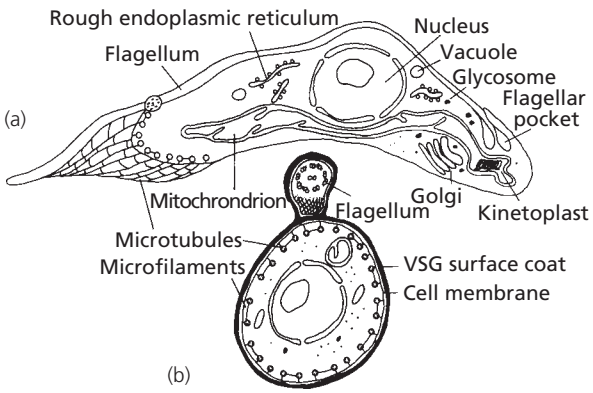

Figure 2 *Ultrastructure of an African trypanosome:* **(a)** *longitudinal section of an intermediate-to-short stumpy blood trypanosome;* **(b)** *cross-sectional view (Redrawn from Seed and Hall 1992, with permission of Academic Press)*

Glycosome

African trypanosomes and related organisms have glycosomes that are membrane-bound assemblies of enzymes that support glycolysis, purine salvage, ether-lipid synthesis, and beta-oxidation of fatty acids. Sequence similarities between genes involved in glycosome and peroxisome biogenesis suggest that these organelles share a common evolutionary origin (Parsons et al. 2001). Enzyme function in the glycosome is considered later in the text.

Variable surface glycoprotein coat and the VSG–glycosylphosphatidylinositiol-specific phospholipase C

African trypanosomes inhabit the blood plasma and, in the case of *T. brucei*, also the interstitial fluids, the lymph, and cerebrospinal fluid. Their extracellular lifestyle presents two unique challenges. First, the parasites must avoid lysis by serum complement factors, a group of enzymes that can assemble into a donut-shaped protein complex on permissive lipid bilayer membranes, leading to loss of the membrane permeability barrier. Secondly, the parasites must evade immune elimination to establish chronic infections. Protection against complement activation and immune elimination is mediated by the variable surface glycoprotein (VSG) coat. In electron micrographs, the coat appears as an amorphous layer 12–15 nm thick on the outer lipid leaflet of the

plasma membrane. On each trypanosome, it comprises about 10^7 VSG molecules encoded by a single VSG gene. The VSG molecules assemble as non-covalent homodimers that stand proud of the membrane (Figure 3). Each VSG monomer is attached to the outer lipid leaflet of the parasites plasma membrane by a glycosylphosphatidylinositiol (GPI) group containing C14 fatty acid tails (Mehlert et al. 1998; Ferguson 1999). The GPI is covalently bound to the VSG C-terminal carboxyl group and the GPI-anchored VSG is free to diffuse in the lateral plain of the membrane. Immune evasion is achieved by antigenic variation of the VSG coat, a process that entails switching among any of a thousand VSG genes and their recombinants of which only one is expressed at a time. Analysis of crystallized VSGs that shared only 16 percent amino acid sequence identity showed that they have highly conserved secondary and tertiary structure (Blum et al. 1993).

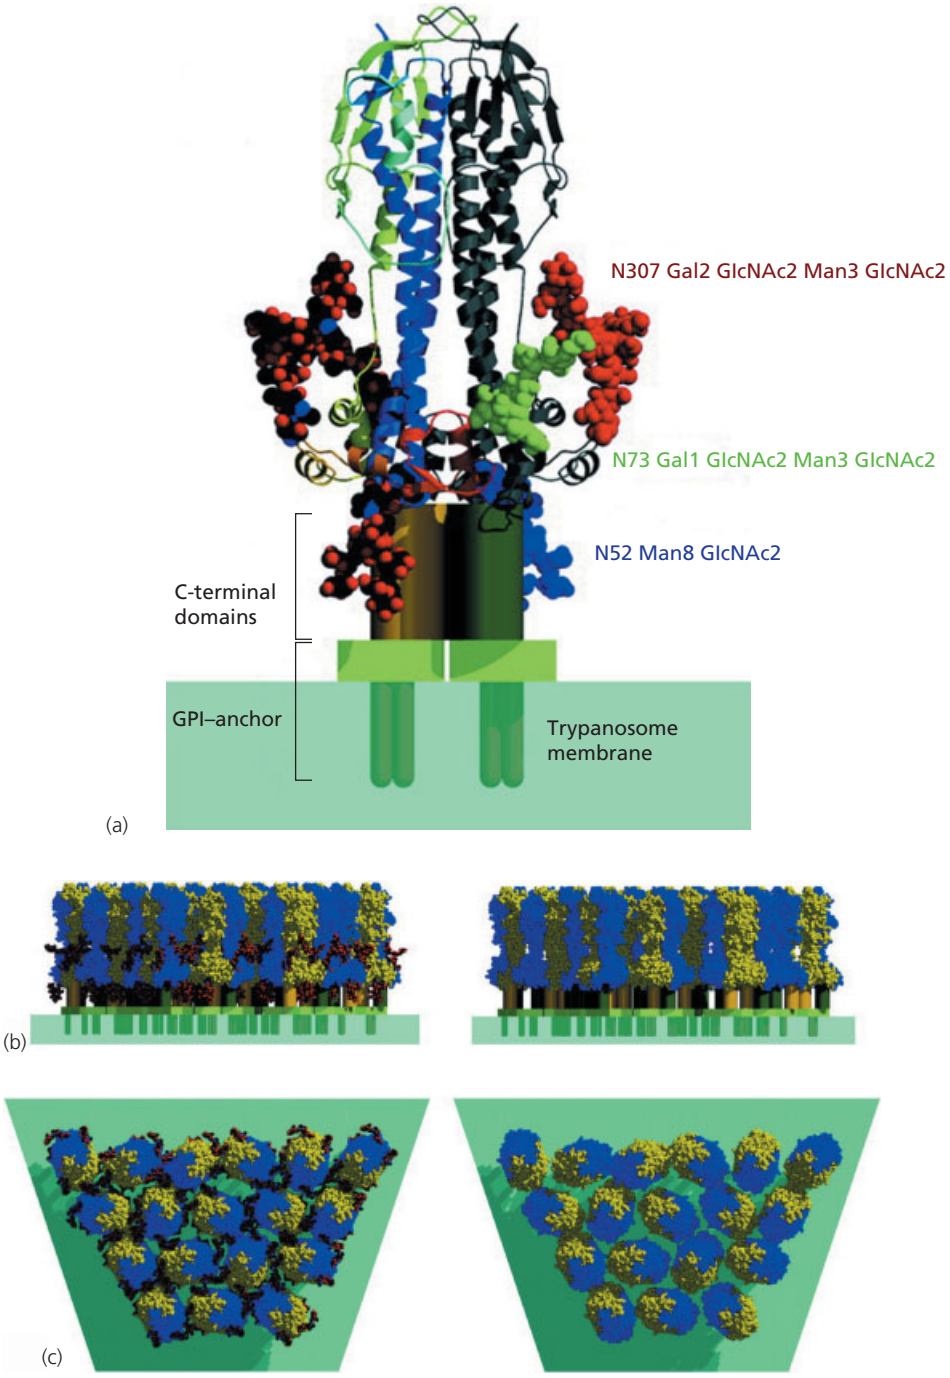

Figure 3 *Molecular models of:* **(a)** *VSG MITat 1.5 with attached, energy minimized, N-linked oligosaccharides;* **(b and c)** *the cell surface coat, viewed from the side and above without (right) and with (left) attached N-linked oligosaccharides (Redrawn from an image by Dr Charles Bond, from Mehlert et al. 2002)*

Consequently, antigenically distinct VSGs assemble into very similar surface coats.

Trypanosomes that are subjected to hypotonic and other stresses release their VSG coat. The released coat lacks its GPI anchor and has an exposed conserved carbohydrate side chain called the cross-reacting determinant (CRD). Release of the VSG is mediated by a VSG–GPI-specific phospholipase (PLC), which is reported to be localized on the cytoplasmic face of vesicles distinct from the endoplasmic reticulum and where it does not normally encounter VSG–GPI. The VSG–GPI-PLC encounters VSG–GPI only under appropriate stress conditions, a process that is thought to involve flipping of VSG from the outer to the inner leaflet of the plasma membrane (Cardoso de Almeida et al. 1999). Conservation of the VSG–GPI-PLC among trypanosomes suggests that it plays an important role in trypanosome biology and/or the parasite–host relationship. However, *T. b. brucei* organisms that are genetically engineered to lack the VSG–GPI-PLC infect and grow in laboratory rodents and tsetse flies. Further studies showed that the organisms do not have a duplicate PLC, suggesting that the VSG–GPI-PLC is not essential for normal *T. b. brucei* function and differentiation events (reviewed in Carrington et al. 1998). However, mice that were infected with the mutant trypanosomes lived for twice as long as those infected with control trypanosomes indicating a role for the enzyme, or for soluble VSG with exposed CRD, in the mammal–trypanosome relationship. The laboratory mouse is not a natural host for *T. brucei*, hence, additional insights into the roles of the VSG–GPI-PLC and released VSG might be gained by studying the behavior of mutant parasites lacking the enzyme in trypanosomiasis-resistant African wildlife species, extant representatives of the hosts in which trypanosomes were selected through evolution.

Additional components of the trypanosome surface

The trypanosome plasma membrane is equipped with transporters for the facilitated diffusion of glucose, pyruvate, and purines. It also has a number of invariant surface glycoproteins (ISG) of unknown function. These are present at about 1 percent of the density of VSG. In addition, the parasite has receptors for host-derived holo- (i.e. iron-loaded) transferrin and serum, and low- and high-density lipoproteins (reviewed by Borst and Fairlamb 1998). The transferrin receptor is encoded by VSG gene expression site associated genes (ESAG) 6 and 7 for which there are several alleles (Steverding 2000). As with VSGs, only one form of the transferrin receptor is expressed at a time by trypanosomes. Although isolation of a receptor for serum low-density lipoprotein has been reported, this was most likely an erroneous assignment (reviewed in Black et al. 2001) and at this time the trypanosome receptors for serum low and high density are not known.

Flagellum and flagellar pocket

African trypanosomes are highly motile. They have a single flagellum, which emerges from an invagination at the posterior end of the cell called the flagellar pocket (Balber 1990) (Figure 4). The structural elements that cause the invagination to form have not been defined. The flagellum comprises an axoneme, a paraflagellar rod, and an attachment zone filament that mediates adhesion to the trypanosome plasma membrane. The flagellum lies in a shallow groove on the cell surface. When the flagellum beats, the attached portion of the cell surface is thrown into folds and gives rise to the undulating membrane visible in the light microscope. The body of the trypanosome has an underlying corset of microtubules that prevent any vesicular exchange with the plasma membrane. This microtubular array is open in the region of the flagellar pocket and at the posterior end of the cell. Although vesicles could transit to or from the cell membrane at either of these zones, endocytosis and exocytosis are restricted to the flagellar pocket region. Bloodstream stage *T. brucei* have much more endocytic activity than other differentiative stages. This is associated with massive upregulation of a clathrin-like heavy chain that is involved in the formation of endocytic vesicles (Morgan et al. 2001).

Trypanosome receptors for host transferrin and serum lipoproteins are thought to be restricted to the flagellar pocket, and to bind ligand that diffuses into the pocket. Indeed, the transferrin receptor has been shown to be restricted to the pocket, at least in organisms that were incubated in the presence of high-affinity transferrin (i.e. donor transferrin) that could bind with high affinity to the receptor. When these same organisms were incubated for 48 hours with low-affinity transferrin, which elevates receptor gene expression, the transferrin receptor was detected over the surface of the parasite. A similar result was obtained using organisms that were engineered to overexpress transferrin receptors and that were incubated in the presence of high-affinity transferrin (Mussmann et al. 2003). These observations were taken to show that the transferrin receptor is held in the flagellar pocket by a saturable mechanism. The transferrin receptor has also been shown to be present in the pocket matrix associated with a gel-like substance. The significance of this dual location is not known. Trypanosome endocytic pathways, endocytic compartments, and sorting signals are the subject of on-going study (Pal et al. 2002). Figure 5 presents a comparison of secretory and endocytic pathways in *T. brucei* and other trypanosomatids. In the case of *T. brucei*, the flagellar pocket and endosomal glycoproteins have been shown to have an attached linear poly-*N*-acetyllactosamine

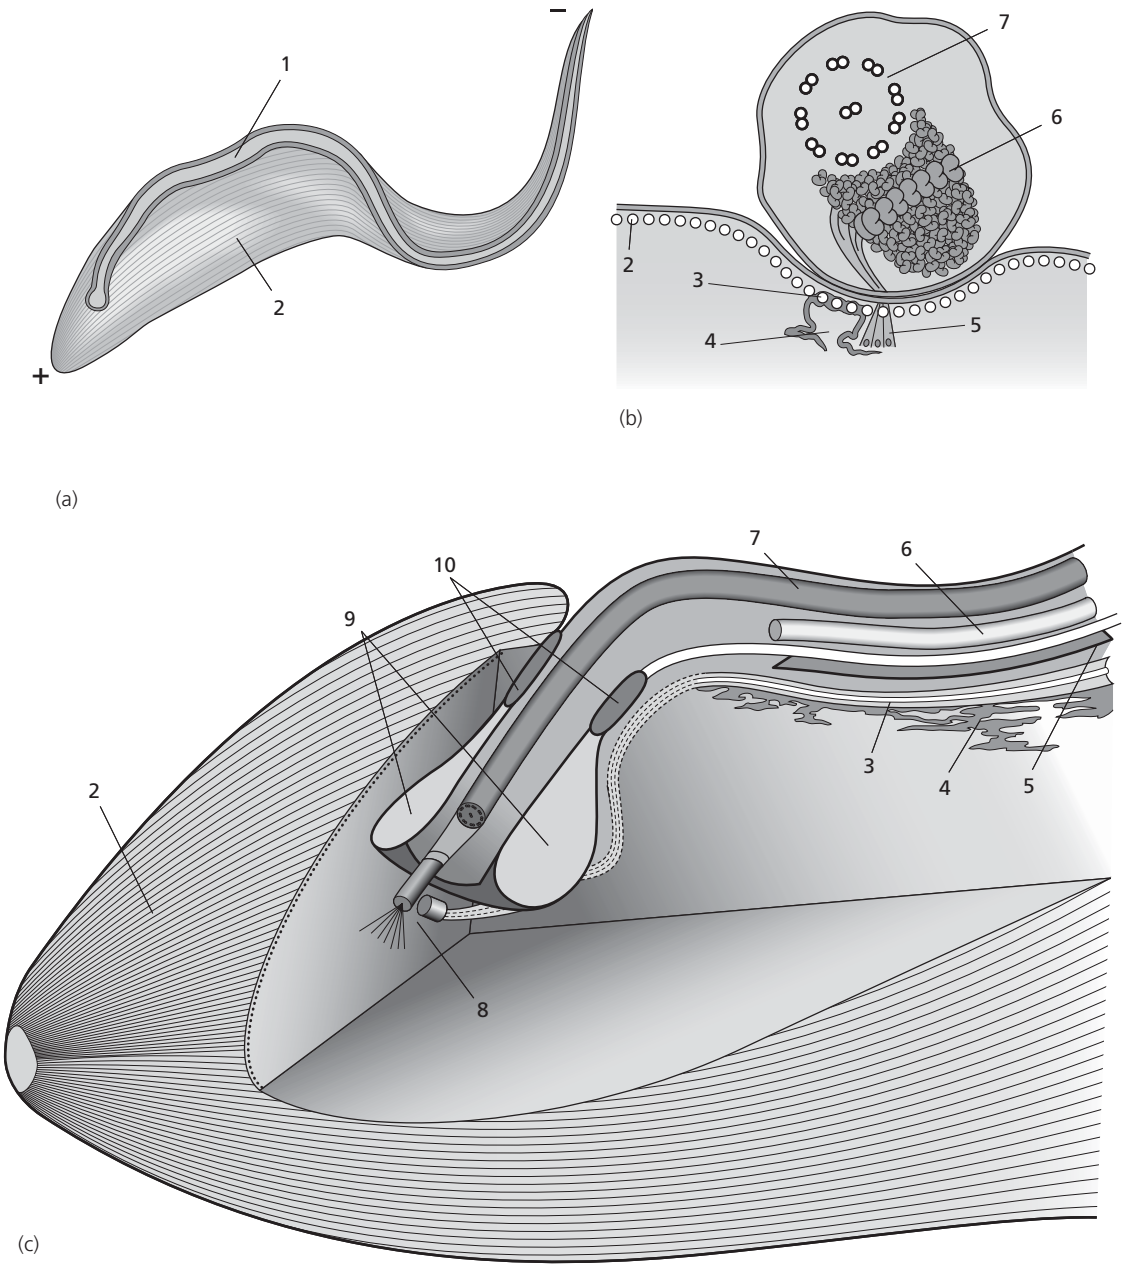

Figure 4 *Schematic illustrations of a trypanosome cell emphasizing the structural components of the cytoskeletion:* **(a)** *detergent-extracted cytoskeleton;* **(b)** *idealized transverse section taken through the midpoint of the cell looking from posterior to anterior;* **(c)** *cut-out view of the flagellar pocket area. moiety, a unique carbohydrate that is developmentally regulated and may be required for endocytosis (Nolan et al. 1999).

Pleomorphism

Bloodstream stage *T. brucei* undergo morphological and biochemical differentiation to non-replicating stumpy forms on reaching peak parasitemia. Stumpy forms have a very truncated flagellum and are greater in diameter than the replicating bloodstream forms. This transition plays a significant role in setting the level of parasitemic waves in infected mammals (Black et al. 1985) and is thought to be directed by endogenous quorum-sensing factors and host-derived growth-inhibitors (Murphy and Olijhoek 2001). The slender to stumpy transition occurs via a series of intermediate forms and *T. brucei* strains that undergo this differentiation are referred to as pleomorphic. Strains that are maintained by passage in

laboratory rodents or in tissue culture in the absence of high molecular weight agarose supplements often lose the property of pleomorphism at least with respect to infections that they give rise to in laboratory rodents, i.e. they remain as replicating slender forms in these hosts. These so-called monomorphic *T. brucei* are typically very virulent and poorly or non-infective for tsetse flies.

Slender form *T. brucei* derive energy solely from glycolysis. In contrast, stumpy form *T. brucei* express α-ketoglutarate dehydrogenase, a Kreb's cycle enzyme, and obtain additional ATP by converting α-ketoglutarate, if supplied to them, to succinate. The partial acquisition of mitochondrial function by stumpy form *T. brucei* is considered to be in preparation for establishing an infection in the tsetse vector.

Life cycle

When an uninfected tsetse bites an infected vertebrate, trypanosomes acquired with ingested blood pass through the esophagus, the crop, and the proventriculus until they reach the midgut. In the fly's midgut, the short stumpy forms complete their morphological and biochemical differentiation into procyclic stages. They complete the development of their mitochondrion, cease synthesizing VSG and express a new coat glycoprotein called procyclin (Mehlert et al. 1998), which facilitates survival and growth in the tsetse fly by mechanisms that are not understood (Ruepp et al. 1997). The procyclic form has a fully functional mitochondrion and consequently differs from the slender bloodstream forms in metabolic activity. The procyclic forms are also elongated with respect to the bloodstream-stage organisms and differ from these in the relative position of the kinetoplast and nucleus.

The trypanosomes have a complex life cycle and a low infection rate in their vectors. It has recently been shown that trypanosomes evoke relatively poor protective immune responses in tsetse flies and other factors are being sought with respect to identifying those that influence infectivity (Aksoy et al. 2002). It is known that age, sex, and genotype of the vector, the type of bloodmeal taken by the vector, and many environmental factors can all influence the susceptibility of the tsetse to the trypanosomes (Maudlin and Ellis 1985; Molyneux and Ashford 1983; Otieno et al. 1983; Vickerman et al. 1988).

After a period of growth in the midgut, the trypanosomes undergo a further series of morphological changes, migrate from the midgut into the endoperitrophic space and finally into the tsetse's salivary glands where they develop into epimastigotes. The epimastigote form is not infective for the mammalian host. The epimastigotes attach to the cells of the salivary gland. They divide repeatedly and then transform into nondividing metacyclic forms, which are small, highly motile, short, and stumpy (Figure 6). They have a terminally located kinetoplast but no free flagellum. When mature, the metacyclic forms detach from the salivary gland cells, synthesize a surface coat of the type found on the bloodstream forms, and become infective to the vertebrate host (Vickerman et al. 1988; Vickerman 1989). The signals for these morphological and

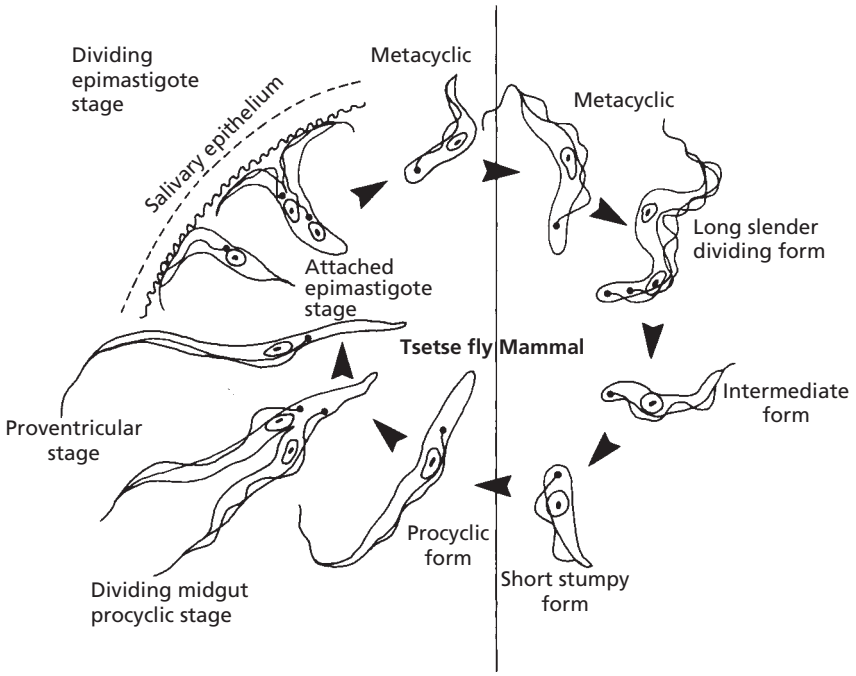

Figure 6 *Life cycle of trypanosomes of the* Trypanosoma brucei *group (Redrawn from Seed and Hall 1992, with permission of Academic Press)*

physiological changes in the trypanosome in its vector are not known. The time required for the trypanosomes ingested by the fly to complete their development in the tsetse and to regain infectivity is approximately 3–4 weeks. However, the length of time will vary depending on the external environmental conditions of humidity and temperature and on the age, sex, and other factors in the tsetse (Molyneux and Ashford 1983). The infective metacyclic forms of the trypanosome are injected into the mammalian host by the biting fly. They transform in the vertebrate host into the long slender trypanomastigote form and increase in number reinitiating the cycle.

BIOCHEMISTRY

In vitro cultivation

The in vitro cultivation of any organism is a prerequisite for any biochemical study and trypanosomes are no exception. Cultivation of procyclic-like *T. brucei* organisms in blood agar medium was achieved early in the 20th century. By the 1970s, semi-defined and defined procyclic culture media had been developed, and by the 1980s, methods were developed for the efficient transformation of bloodstream-stage *T. brucei* into procyclic forms in vitro. Typically, incubations are at 27°C in serum-supplemented medium further supplemented with citrate and *cis*-aconitate (Brun and Jenni 1985; Kaminsky et al. 1988). The signal pathways that are regulated by the drop in temperature and presence of citrate and *cis*-aconitate are not resolved. Procyclic form *T. brucei* can undergo further differentiation in vitro to give rise to mammal-infective metacyclic form trypanosomes (Hirumi et al. 1992). The signaling systems that regulate this differentiation are also not known. Propagation of bloodstream-form *T. brucei* in vitro was achieved in 1977 following a heroic checkerboard comparison involving several media, sera, and fibroblast feeder-layer cells with respect to their *T. b. brucei* growth-supporting capacity (Hirumi et al. 1977). Axenic culture conditions were subsequently established by supplementing culture medium with cysteine or a reducing agent, β2-mercaptoethanol. It is now known that cysteine is an essential growth factor for the parasites (Duszenko et al. 1992). Cysteine is readily oxidized to cystine in the presence of copper, and survival and growth of bloodstream-stage *T. brucei* in vitro is enhanced by inclusion of the copper chelating agent bathocuproine in culture medium. The ability to grow trypanosomes in axenic cultures has greatly facilitated analysis of cell function and biochemistry both by providing controlled experimental conditions, and by expediting the development of mutant organisms through the use of genetic engineering techniques. Gene disruption and addition mutants have been developed, as have organisms expressing inhibitory RNA. These mutant cell lines are a valuable resource in elucidating pathways that regulate endocytosis and exocytosis, VSG switching, and other critical processes.

Not all strains of *T. brucei* grow as bloodstream-form organisms in tissue culture medium, and among those that do there is a high tendency to lose the pleomorphic

phenotype. However, it has recently been found that the inclusion of high molecular weight agarose in the medium facilitates both growth of the parasites in vitro and retention of pleomorphism (Vassella and Boshart 1996). The mechanism underlying the effect is unknown. A serum-free culture medium has also been described for *T. b. brucei* (Hirumi et al. 1997). This medium is supplemented with fatty acid-free albumin and serum lipoproteins, components that are required for progression of the parasites through G_1 of their cell division cycle (Morgan et al. 1996) as well as bovine alpha 2 macroglobulin, which has an undefined function with respect to *T. brucei*. Serum lipoproteins are complexes of apolipoproteins, phospholipids of several types, cholesteryl esters, triglycerides, and cholesterol. It is not known which, or how many, of these components are required to drive progression of the parasites through G_1 of their cell division cycle.

Energy metabolism

The blood stage trypanosomes have a high rate of glucose catabolism. As mentioned above, the glycolytic enzymes carrying out this process are present in a unique microbody-like organelle called the glycosome. An outline of glucose metabolism is shown in Figure 7. Under aerobic conditions, glycerol-3-phosphate is produced from dihydroxy-acetone-phosphate during which process NADH is oxidized to NAD. The glycerol-3-phosphate moves from the glycosome to the parasite's mitochondrion where it is converted back to dihydroxy-acetone-phosphate by glycerol-3-phosphate oxidase. The dihydroxy-acetone phosphate re-enters the glycosome and is further metabolized. Under aerobic conditions, glucose is exclusively converted to pyruvate, which is exported by a pyruvate transporter or transaminated and exported as alanine or utilized in protein synthesis. Under anaerobic conditions, glycerol-3-phosphate cannot be converted back to dihydroxy-acetone-phosphate, hence glucose metabolism results in equal portions of pyruvate and glycerol being produced and exported. In bloodstream *T. brucei* the nine enzymes involved in the conversion of glucose into phosphoglycerate or glycerol account for more than 90 percent of the protein in the glycosome (Hannaert and Michels 1994; Opperdoes 1987; Opperdoes et al. 1990).

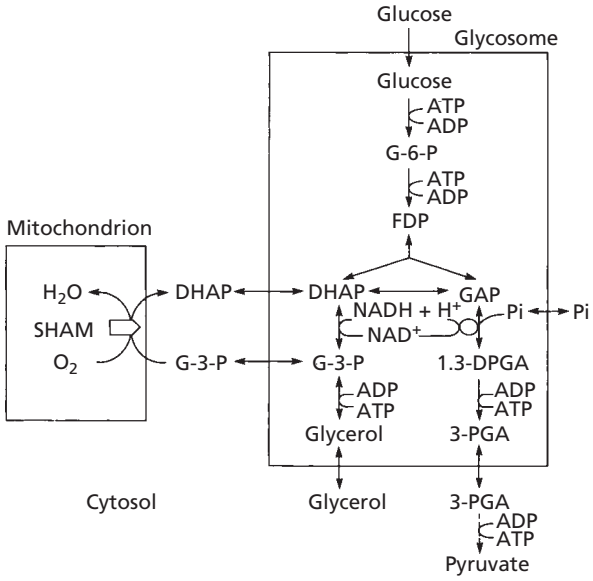

Figure 7 *Glucose metabolism in the bloodstream form of African trypanosomes (From Opperdoes 1987)*

The compartmentalization of the trypanosome's glycolytic enzymes in the glycosomes is a pattern different from that occuring in other eukaryotic organisms where the enzymes involved in glycolysis are present in the cytoplasm. It has been suggested that the close physical association of the glycolytic enzymes in the glycosome and their high concentration there account for the very high rate of glucose catabolism by the blood-stage parasites (Hannaert and Michels 1994; Sommer and Wang 1994). However, model data obtained using a kinetic computer replica of glycolysis in *T. brucei* did not support this idea. Rather, the model suggests that compartmentalization may serve to prevent glycolytic intermediates accumulating to dangerous levels in the trypanosome cytosol, and to facilitate recovery from glucose deprivation (Bakker et al. 2000).

The procyclic forms are adapted to the environment of the vector, which is entirely different from the environment that the blood-forms inhabit. In the procyclic forms, the mitochondrion becomes functional; it has cristae, and contains the tricarboxylic acid cycle enzymes, cytochromes, and cytochrome-dependent respiratory chain enzymes, all of which are absent from the slender bloodstream-forms. The procyclic form has a much lower rate of glucose catabolism than does the slender bloodstream-form. Phosphoenolpyruvate is carboxylated by procyclics to form oxaloacetic acid with subsequent conversion to malate, fumarate, and succinate. The major end products of glucose utilization by the procyclic forms are succinate, acetate, carbon dioxide, and alanine. ATP is generated primarily by oxidative phosphorylation. Amino acids, particularly proline, are the primary substrates used by the procyclics to obtain energy.

Both bloodstream-stage and procyclic *T. brucei* lack key enzymes necessary for classical glyconeogenesis, and both lack the enzymes of the Entner–Douderoff pathway (Cronin et al. 1989).

Redox-regulation

Trypanosomes, like other eukaryotic cells, use NADPH as their major source of reducing power. This is produced in the pentose–phosphate pathway. All the

enzymes of this pathway have been found in *T. b. brucei* (Cronin et al. 1989). Glucose-6-phosphate dehydrogenase, the sentinel that sits at the gateway of the pentose–phosphate pathway has been demonstrated to localize to the glycosome, and the gene encoding the downstream enzyme 6-phospho-gluconolactonase contains a C-terminal peroxisome targeting signal consistent with a likely localization in the glycosome (Duffieux et al. 2000). The trypanosomes possess the enzymes required to produce d-ribose-5-phosphate for nucleic acid synthesis and NADPH for other synthetic reactions. However, there are differences between the procyclic forms and blood-forms in the enzymes of the non-oxidative segment of the pentose–phosphate pathway. Bloodstream-stage *T. brucei* suppress expression of genes encoding ribulose-5-phosphate 3′-epimerase and transketolase (Cronin et al. 1989) and thus terminate their NADPH-yielding pentose–phosphate pathway at ribulose-5-phosphate instead of recycling this product back into the glycolytic pathway. Consequently, the glucose metabolic pathways in bloodstream-stage *T. brucei* appear to be configured to yield ATP or NADPH but not both at the same time. The evolutionary advantage accrued by the trypanosomes through adopting this unusual arrangement is not known.

Trypanosomes spontaneously generate hydrogen peroxide as a result of energy metabolism. They are also exposed to hydrogen peroxide and superoxide anion that are produced by their mammal hosts. The parasites have an Fe-superoxide dismutase that catalizes the reduction of superoxide anion to hydrogen peroxide. However, they lack catalase and rely on coupled redox reactions fueled by the reducing power of NADPH to inactivate hydrogen peroxide (Fairlamb and Cerami 1992; Flohe et al. 1999). The utilization of NADPH deflects glucose-6-phosphate from the glycolytic to the pentose–phosphate pathway by unleashing glucose-6-phosphate dehydrogenase. This may account for the almost instantaneous depletion of the ATP content of bloodstream-stage trypanosomes that occurs when the parasites are placed under oxidative stress (Muranjan et al. 1997). Hydrogen peroxide metabolism by *T. brucei* and other kinetoplastid flagellates involves 'a cascade of three enzymes, trypanothione reductase, tryparedoxin, and tryparedoxin peroxidase… The terminal peroxidase of the system belongs to the protein family of peroxiredoxins, which is also represented in Entamoeba and a variety of metazoan parasites' (Flohe et al. 1999).

Amino acid synthesis

There has been relatively little study of amino acid synthesis and utilization by trypanosomes, but it appears that the organisms have limited ability to synthesize amino acids de novo. A majority of the amino acids required by trypanosomes must either be formed by a salvage pathway such as that bringing about the transamination of pyruvate, oxaloacetic, and α-ketoglutarate to alanine, aspartic, and glutamic acids, respectively, or be directly supplied by the host (Gutteridge and Coombs 1977).

Some amino acids are used for purposes other than protein synthesis. In the procyclic forms, proline is used as a respiratory substrate, and threonine may serve as the preferred substrate for formation of acetyl coenzyme A, which is required for the elongation of fatty acid chains. The only enzymes involved in amino acid metabolism that have received extensive study are those bringing about aromatic amino acid catabolism and those for the use of ornithine in the synthesis of polyamines. The polyamines are known to be important in the proliferation and differentiation of the blood-stage trypanosomes. Inhibition of putrescine and spermidine synthesis blocks trypanosome division and causes changes in cellular morphology (Pegg and McCann 1988).

Purine synthesis

Neither the blood-form nor the procyclic form of the trypanosomes synthesize purines de novo; they require salvage mechanisms to obtain them (Hammond and Gutteridge 1984). Most of the enzymes of the salvage pathway are located in the cytoplasm, and hypoxanthine–guanine phosphoribosyl transferase is found in the glycosome. The trypanosomes can synthesize pyrimidine by a pathway which appears similar to that used by mammalian cells, although there are two differences: (i) in mammals, the enzyme dihydroorotate dehydrogenase is present in the mitochondria but in trypanosomes it is present in the cytosol; (ii) in the trypanosomes, the last two enzymes of the pathway (orotate phosphoribosyl transferase and orotidine 5-phosphate decarboxylase) are in the glycosome rather than in the cytosol as in mammals (Fairlamb 1989).

Lipids

Bloodstream-stage *T. b. brucei* have a limited ability to synthesize lipids and generally depend on the host for fatty acids, phospholipids, cholesterol, and other lipids (reviewed in Mellors and Samad 1989). They obtain phospholipids, lysolipids, cholesterol, and cholesteryl esters from serum low- and high-density lipoproteins (Vandeweerd and Black 1989) and remodel the phospholipids by removing and replacing fatty acids in the sn1 and sn2 positions (Mellors and Samad 1989). The bloodstream-stage parasites also synthesize myristate (Morita et al. 2000), which they preferentially use to remodel the glycosyl-phosphatidylinositol anchor that

holds their glycoprotein coat in the outer leaflet of the plasma membrane.

The trypanosome plasma membrane contains domains with detergent extraction properties shared with the lipid rafts of higher eukaryotic cells. Most of the VSG may be associated with these putative rafts (Denny et al. 2001) and there is evidence that the putative rafts are enriched in the flagellar membrane of the parasites (Toriello et al. 2002).

MOLECULAR BIOLOGY AND GENETICS

The general organization of trypanosome nuclear DNA has been succinctly described by Donelson (2001).

> *Trypanosoma brucei* is a diploid organism with a nuclear haploid DNA content of 35 ± 9 megabase (Mb) pairs depending on the trypanosome isolate. About 15 percent of total cellular DNA is in the kinetoplast... The remaining 85 percent occurs in the nucleus as linear DNA molecules ranging in size from 50 kb to 6 Mb. At least 11 pairs of megabase chromosomes of 1–6 Mb exist that are numbered I–XI from smallest to largest. The two homologues of a megabase chromosome pair can differ in size by as much as 4-fold. Several intermediate-sized chromosomes of 0.2–0.9 Mb and uncertain ploidy are also present... [and there are about 100 minichromosomes]. About 50 percent of the nuclear genome is coding sequence. To date, only one tRNA gene and one protein-encoding gene have been found to contain an intron. [Significant portions of the genome have now been sequenced]... Based on analogy with the *Leishmania* genome, much of the African trypanosome nuclear genome is likely to be arrayed as long transcription units of 50 or more intronless genes.

Chromosomal DNA of all eukaryotes is folded with nucleosomes that are composed of core histones H2A, H2b, H3, and H4. These are highly conserved from yeast to humans but are much more diverse in trypanosomatids. However, there is a degree of sequence conservation suggesting that the overall structure of the *T. brucei* nucleosome is probably similar to that of other eukaryotes (reviewed in Horn 2001). For example, lysine residues are conserved in the N-terminal tails of the core histones of *T. brucei* and higher eukaryotes and may be targets for covalent modifications that affect chromatin structure. Acetylation, phosphorylation, ubiquitination, and methylation of the N-terminal tails of core histones are known to regulate chromatin structure in higher eukaryotes. Nevertheless, chromatin remodeling in *T. brucei* does not fully mimic that in higher eukaryotes. For example, phosphorylation of serine 10 in histone H3 is involved in chromosome condensation in many eukaryotes. However, this amino acid residue is absent from the N-terminal tail of *T. brucei* histone, which may account for the absence of chromosome condensation during trypanosome mitosis.

In higher eukaryotes, nucleosomes form bundles as a result of the binding of linker histone H1 to linker DNA flanking the nucleosome core. *T. brucei* organisms also have linker histone H1 but this has a simple repetitive sequence and is not precisely analogous to that of higher eukaryotes (reviewed in Horn 2001). The level of histone H1 is higher in the bloodstream-forms than in procyclic *T. brucei*, a larger number of H1 variants is expressed and the H1–chromatin association is stronger in the bloodstream-forms (Schlimme et al. 1993) possibly associated with a greater need to stabilize chromatin at the higher temperature encountered in the mammal host.

Sequence information in the *T. brucei* genome database indicates that the parasites also have deacetylases, acetyltransferases, and bromodomain proteins (reviewed in Horn 2001). These proteins affect chromatin by removing groups that covalently modify histones and DNA, and there is evidence that they act as transcription regulators in higher eukaryotes. Perhaps they perform a similar function in trypanosomes. There is evidence that differences in chromatin accessibility may account for developmentally regulated gene expression in *T. brucei* (Navarro et al. 1999).

There is considerable evidence that exchange of genetic information can occur in the African trypanosomes, and that this exchange occurs in the vector's salivary glands, but not in the tsetse gut form or in the mammalian host. The evidence suggests that genetic exchange involves a meiotic division. However, a haploid trypanosome stage has not been identified (reviewed in Gibson 2001b). Genetic exchange has been demonstrated between the various *T. brucei* subspecies, but in the case of *T. b. gambiense* was observed with the relatively virulent so-called group 2 parasites that transmit through the tsetse fly. The less virulent group 1 *T. b. gambiense* do not transmit readily through the fly. The relevance of genetic exchange to the survival and function of *Trypanozoon* organisms is far from clear. In this regard, group 1 *T. gambiense* and *T. evansi*, neither of which are tsetse transmitted, survive quite well without it. Nevertheless, it is apparent from the analysis of isoenzyme patterns, as well as RFLP among different *T. brucei* stocks, that sexual recombination does occur among trypanosomes in the field.

There is debate as to the ploidy of the trypanosomes. The results of isoenzyme and RFLP analysis of genetic crosses between trypanosome clones suggest that the trypanosomes are generally diploid. However, there is evidence to suggest that some hybrids may be triploid and that changes in chromosome size may occur during genetic exchange (Kooy et al. 1989; Gibson et al. 1992). Indeed, 'hybrids with a DNA content of either 2*n* or 3*n*

(but not intermediate amounts) have been found in five of six crosses for which DNA contents have been measured, suggesting that trypanosome DNA is inherited in packets of *n*' (reviewed in Gibson 2001b).

Cell division

In the African trypanosomes, the nuclear membrane does not break down during cell division and chromosomes do not condense. However, as would be expected, chromosomal reorganization does occur as determined by the location of chromosome ends, i.e. telomeres. During interphase, telomeres are located around the periphery of the nucleus in nondividing stumpy form *T. brucei*, and the insect procyclic form, but in the center of the nucleus in dividing bloodstream-forms. The distinct orientation of telomeres in bloodstream-stage trypanosomes may be required for expression of VSG genes as the expression sites are telomeric. At the onset of mitosis, in all trypanosome life cycle stages the telomeres congregate in a central zone of the nucleus and split into two clusters that migrate to opposite nuclear poles. The double-ended nucleus then divides and the telomeres reorganize to the foci present during interphase. During migration, the telomeres are located at the free end of the mitotic spindle, which is contained within the nuclear membrane. The mechanism of chromosome segregation is discussed by Ogbadoyi et al. (2000) and Perez-Morga et al. (2001) and readers are referred to these papers for further information.

RNA editing

RNA editing (i.e. 'the alteration of RNA sequences by base modifications, substitutions, insertions, and deletions') was first described in trypanosomes and has since been identified in other eukaryotes including humans (reviewed in Horton and Landweber 2002). RNA editing in trypanosomes is mediated by guide RNAs that are encoded in the kinetoplast minicircles. These direct the insertion and deletion of U, thus converting mRNA transcribed from so-called 'cryptogenes' into functional gene products. RNA editing can be a cumbersome process sometimes involving multiple guide RNAs, sequentially applied, to edit a single mRNA, and presumably had selective value to be retained. Possible advantageous properties of the process include the stable maintenance of otherwise deleterious mutations in DNA genomes, improved storage of information in crowded genomes, and novel posttranscriptional modes of genetic regulation.

Transplicing

All trypanosome mRNAs are capped with a 39-nucleotide structure that is added at the 5′ end of pre-mRNA by trans-splicing. The totally conserved 39-nucleotide structure, called the spliced leader or mini-exon, is trimmed from an approximately 100-nucleotide nontranslated RNA that is transcribed from a set of nonidentical genes in the trypanosome genome. The regulation of this process is not known. The spliced leader is subsequently attached to each protein-coding sequence present in long polycistronic precursors. This process is an essential step in the biosynthesis of trypanosome mRNAs.

VSG antigenic variation

Trypanosomes contain within their genome over 1 000 different VSG genes. In addition, new variant antigen types (VAT) are created by VSG gene mutations and recombination. With a few special exceptions, each trypanosome expresses only a single VSG on its surface at any given time. This is encoded by a single VSG gene that is expressed at a telomeric expression site. Unexpressed VSG genes are found throughout the trypanosome genome including on minichromosomes and in unexpressed VSG-gene expression sites. There are 20 expression sites for bloodstream-stage trypanosome VSG genes present in the genome, of which only one is active at a time. The promoter for the expressed VSG gene is upstream of and separated from the expressed VSG gene by at least eight ESAGs. Analyses carried out using trypanosomes expressing the AnTat 1.3 VSG show that the ESAGs and expressed VSG are transcribed as one polycistronic unit (Vanhamme et al. 2001). Although only one of the possible 20 bloodstream-stage trypanosome VSG-gene expression sites is fully expressed at a time, transcripts of ESAG 6 from unexpressed expression sites has been recorded (Ansorge et al. 1999). Switching of the expressed VSG gene requires exchange of VSG genes within an active expression site, or silencing of an active expression site and activation of another. Mechanisms of VSG gene switching and expression site silencing are reviewed by Cross et al. (1998) and Borst and Ulbert (2001) and readers are referred to these reviews for further information.

Metacyclic *T. brucei*, i.e. the infective form transmitted from tsetse to the mammal host, are also coated with VSG (Barry et al. 1998). The genes that encode metacyclic VSGs are distinct from those of bloodstream-form organisms and only 27 have been identified. Each metacyclic VSG gene is located at the end of a large chromosome and expression does not require DNA rearrangements. The diversity of metacyclic VSG genes may have evolved to permit multiple reinfection of hosts. Although there are many fewer metacyclic VSG genes than bloodstream-form VSGs, it is unlikely that a metacyclic VSG vaccine will be effective. The expressed metacyclic VSG repertoire has been observed to change over time (Barry et al. 1983).

Transferrin receptor variants

Transferrin is a required growth factor for trypanosomes and is acquired by receptor-mediated endocytosis using receptors that are distinct from mammalian counterparts and are encoded by genes ESAG 6 and 7, which are upstream of the VSG-gene expression site. ESAG 6 and 7 gene products are structurally similar to the N-terminus of VSGs suggesting that they arose from a VSG gene. ESAG 7 encodes a polypeptide of 340 amino acids while ESAG 6 encodes one of 401 amino acids. Only the latter has a carboxy-terminal GPI-addition signal. Hence, the assembled heterodimeric receptor is held in the membrane by only a single GPI. This dimer binds transferrin. It is about 75 percent of the size of a VSG dimer and may be buried in the VSG layer in such a way that its ligand-binding site is accessible to transferrin but the rest of the receptor is not accessible to antibody. The affinity of binding depends on the donor origin of the transferrin, and on the bloodstream-form trypanosome VSG expression site used. Different transferrin receptor alleles associated with different VSG-gene expression sites encode similar but not identical receptors resulting in variation in affinity for transferrins from different mammal host species. This flexibility may allow trypanosomes to escape binding-site-specific antibodies and to meet the needs of the parasites for transferrin acquisition in a particular host. In this regard, antibody specific for the transferrin receptor selectively affected the in vitro growth of parasites expressing receptors with low affinity for the transferrin type present in the culture medium (Gerrits et al. 2002). While discouraging from the point of view of vaccinology, this result suggests that the receptor is directly accessible to antibody, supporting the view that not all molecules that are critical for trypanosome function are obscured by VSG.

CLINICAL ASPECTS

The cell and molecular biology of African trypanosomes is so fascinating that it is sometimes possible to forget that the organisms are devastating pathogens. However, this is not a luxury afforded to the victims of sleeping sickness. *T. b. rhodesiense* and *T. b. gambiense* both cause fatal disease. However, there are differences in the clinical manifestations of the diseases they cause and in their epidemiology (Table 1). The disease produced by *T. b. gambiense* (also called West African trypanosomiasis) is chronic in nature lasting up to 4 years, whereas the disease produced by *T. b. rhodesiense* is more acute, rarely lasting more than 9 months before death occurs. The molecular basis for this difference in virulence is not known.

As noted earlier, one of the key aspects of African trypanosomiasis is the phenomenon of antigenic variation that results in waves of parasitemia occurring in the blood of infected people and animals (Figure 8). The clinical aspects of trypanosomiasis and the chronic nature of the disease can be attributed to these waves of parasitemia.

Phases of the disease

African trypanosomiasis in humans can be separated into three phases (Table 2).

PHASE 1

The first phase occurs just after the inoculation of the metacyclic trypomastigotes by biting tsetse flies. A chancre develops at the site of the bite, and the trypanosomes remain at this site for a short time. There is inflammation of the subdermal tissue at the site, with edema, erythema, tenderness, and heat. The chancre is

Characteristic	*T. b. gambiense*	*T. b. rhodesiense*
Disease	Chronic	Acute
	Low parasitemia	High parasitemia
	Incubation period is months to years	Incubation period is days to weeks
Main tsetse vector	*G. palpalis* group	*G. morsitans* group
	G. palpalis	*G. morsitans*
	G. fuscipes	*G. pallidipas*
	G. tachinoides	*G. swynnertoni*
Transmission	Human reservoir	Animal reservoir
	– (primary)	– (primary)
	Riverine tsetse	Savanna and woodland tsetse
	– (secondary)	– (secondary)
	Animal reservoir	Human reservoir
Reservoir hosts	Possibly kob, hartebeest, domestic pigs, dogs	Bushbuck, other antelope, hartebeest, hyena, lion, domestic cattle; possibly warthog and giraffe
Geographical range	West Africa, western, and northern Central Africa	East Africa and north Central Africa

a) Reviewed in Seed and Hall (1992)

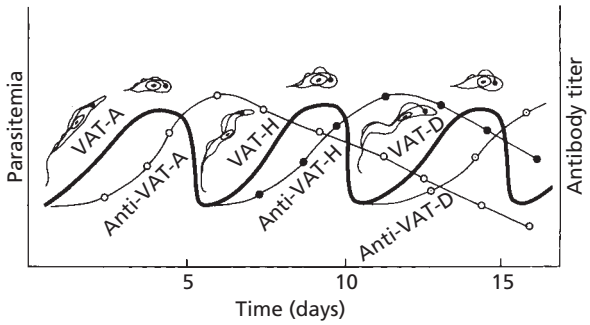

Figure 8 *Waves of parasitemia and their relationship to the humoral response in a mammalian host infected with the African trypanosomes. The first wave consists of a trypanosome population in which the major variant antigen type is VAT-A. This wave of parasitemia is followed by an antibody response (antiVAT-A) whose peak titer is observed shortly after the wave of parasitemia is cleared. A minor VAT (VAT-H) present on some trypanosomes from the preceding population gives rise to the next wave of parasitemia. This population is later cleared by host antiVAT-H. The rise and fall of trypanosome populations continues throughout the life of the infected host. In experimentally infected rodents or rabbits, a peak in parasitemia is observed every 5–7 days. Infected rabbits may live for as long as 6 months, during which time they may experience as many as 30 waves of parasitemia. (From Seed and Hall 1992, with permission of Academic Press)*

more readily observed in white people than in black people and is most frequently found in individuals infected with *T. b. rhodesiense*.

PHASE 2

During the second phase the trypanosomes spread throughout the entire body. They move through the blood and lymphatic vessels and multiply rapidly. Clinical symptoms during this stage appear to be associated with the waves of parasitemia. The high parasitemias are accompanied by fever, headache, joint pain, and malaise (Molyneux et al. 1984). These clinical symptoms may decrease in intensity as the disease becomes chronic. Splenomegaly and lymphadenopathy are major features of this stage of the infection. Histopathological examination of the lesions shows vasculitis with edema and perivascular infiltration of leukocytes.

PHASE 3

Humans infected with the African trypanosomes, if untreated, eventually develop central nervous system (CNS) disorders. They may develop a wide array of behavioral changes ranging from aggressiveness to sleep-like states. The final stage involves complete somnolence (sleeping sickness). The common clinical symptoms of third-phase infection result from damage to the heart, nervous system, and other organs.

IMMUNOLOGY AND PATHOLOGY

Trypanosomiasis-susceptible hosts

Sequential microscopic and serologic analyses of blood from infected patients and experimental animals have shown that African trypanosomiasis is characterized by recurring waves of parasitemia. Each rise in parasitemia is paralleled by an increase in antibody specific for major variant antigenic types in the wave. The variant specific antibody is involved in the removal or clearance of a major portion of the trypanosome population from the blood and other body fluids, a process that ends each wave of parasitemia. Although this specific antibody clears a large majority of the trypanosomes present during a given wave of parasitemia, there pre-exists within that population a minor population of trypanosomes with a different VSG. This minor population gives rise to the next wave of parasitemia. New surface coat variants appear at frequencies of 1 in 10^6 cells in syringe-passaged populations and an estimated 1 in 100 cells in fly-passaged field isolates. Antibody therefore acts as a selecting agent removing the major VSG popu-

Table 2 *Some common clinical symptoms of African trypanosomiasis of humans*

Stage of infection	Symptoms [a]
Fly bite, chancre	Localized tenderness and erythema at site of fly bite
Early parasitemic stage	Headache, joint pain, fever, lymphadenopathy, weight erythema, itching, anemia, dizziness
Later stages – symptoms associated with particular organ systems	
Edema	Peripheral ascites, lung edema, pericardial effusion
Nervous system	Waking EEG changes and sleep–wake cycles[b,c], insomnia/somnolence, mental disorders, slurred speech, paralysis, brisk reflexes, epileptiform fits
Cardiac system	ECG changes, congestive heart failure
Endocrine system	Amenorrhea and impotence with hypogonadism[d], altered thyroid function[e], adrenocortical function[f], and changes in the circadian rhythms of plasma cortisol and prolactin[g]
Other	Puffy facial appearance, diarrhea, anorexia, splenomegaly

a) For further details, see Seed and Hall (1992), b) Buguet et al. (1993), c) Hamon et al. (1993), d) Soudan et al. (1993), e) Reincke et al. (1993), f) Reincke et al. (1994), g) Radomski et al. (1995).

lation and allowing for other VATs that exist in the population to increase in number. VSG gene switching and antibody selection of variants results in the appearance of new peaks in parasitemia every 5–10 days (Figure 8). There is evidence that tumor necrosis factor, which is elaborated by macrophages in infected animals, can also kill trypanosomes, but this action appears to be restricted to one or a few isolates and may therefore be of limited significance (Kitani et al. 2002).

Trypanosome-infected mammals first make VSG-specific antibodies of the IgM class. These facilitate trypanosome clearance in two ways:

1. by promoting assembly of complement components on the parasite surface to yield a membrane attack complex, which lyses the parasites
2. by causing opsonins, namely, complement fragments C3b and iC3b, to be deposited on the parasite surface resulting in their binding to complement receptors on macrophages and neutrophils and their phagocytosis.

It has been shown experimentally that the VSG-specific IgM immune response is primarily a B-cell response of a type that, in mice, does not require T-cell help. However, T-cell-dependent IgG responses also arise in infected animals. VSG-specific antibodies of the IgG class are thought to play an important role in clearing trypanosomes from tissue fluids because IgG is smaller than IgM and can diffuse more readily into the tissues.

The development of broad, and possibly polyclonal, B-cell activation and macroglobulinemia are among the defining characteristics of trypanosomiasis. Both antihost and antitrypanosome antibodies are present in the sera of infected patients and contribute to the macroglobulinemia. After the disease has persisted for some time, the lymph nodes and spleen become enlarged. There is also CNS involvement. Large numbers of white cells are found in the cerebrospinal fluid, which contains high levels of IgM and other proteins, especially during the late stages of the disease (Haller et al. 1986; Molyneux et al. 1984). The presence in brain tissue of 'Morula cells of Mott', which are plasma cells with highly distended sacs of endoplasmic reticulum, was once considered pathognomic of sleeping sickness.

Many signs of disease appear in infected trypanosomiasis-susceptible hosts. There are inflammatory lesions in the heart and brain with perivascular infiltration by lymphocytes, plasma cells, and monocytes. In chronically ill patients, there may be chronic inflammation of muscle and nerve fibers. In patients with advanced disease, these changes lead to edema and fibrosis. Pathology, visible by microscopic examination, has also been seen in the lungs, spleen, and liver. In the blood, there is a reduction in the numbers of erythrocytes and platelets, and a reduction in hemoglobulin content. Edema and hemorrhage develop, due to changes in the vascular beds of the heart and brain. In the CNS, there is demyelination and neuronal damage that may extend into the white matter. The perivascular cuffing and inflammatory cell infiltration extend deep into the choroid plexus. As the disease progresses, chronic meningoencephalitis occurs. Changes in electroencephalograms and diurnal sleep patterns have been detected in chronically infected humans (Bentivoglio et al. 1994; Buguet et al. 1993; Hamon et al. 1993).

Experimental data from studies of infected laboratory animals suggest that the encephalopathy observed in patients with advanced trypanosomiasis has an immunological basis (Jennings et al. 1989). It can be observed, for example, that many aspects of the pathology of African trypanosomiasis are similar to those present in animals undergoing a progressive Arthus-type reaction. For example, high immunoglobulin levels and large quantities of immune complexes are present in the blood and the CNS of experimentally infected animals and infected humans. In addition, high kinin levels with changes in prothrombin activity as well as changes in the levels of fibrin, fibrinogen, and complement have been reported to occur in patients as well as in experimental animals suffering from trypanosomiasis (reviewed in Seed and Hall 1992). These last changes are not only consistent with those occurring during an Arthus reaction, but also with those induced by the activation of the coagulation system as occurs in patients with the disseminated intravascular coagulation often present in patients with the Rhodesian form of this disease. Furthermore, antiCNS components (galactocerebrosides, neurofilaments, tryptophane) have been described in sera and cerebrospinal fluid (CSF) of sleeping sickness patients (Dumas and Bouteille 1996). These may arise as a result of cross reactions with common epitopes between host and trypanosomes or from a breakdown in immune regulation leading to autoimmunity. All of these changes, and others including the changes reported to occur in cytokine levels of patients, are suggestive of an immunologically mediated pathology in trypanosomiasis. Furthermore, the reactive arsenical encephalopathy that occurs in 3–5 percent of late-stage infection patients treated with melarsoprol may also have an immunological basis (Adams et al. 1986; Haller et al. 1986), which is the rationale for the use of anti-inflammatory corticosteroids in the treatment of these patients (Jennings et al. 1989).

Although immunoglobulin levels are increased in humans with trypanosomiasis and their immunological system is very active, it has been found that infected humans respond to secondary infections as if they were immunosuppressed. Such immunosuppression in patients with trypanosomiasis is well documented (Greenwood et al. 1973). The actual mechanisms involved are unknown but there are a number of reasonable suggestions based on data from animal studies. Impaired B-cell responses may result from overactivation and clonal depletion, and from a loss of immune system follicular

structure during infections. It is unclear whether unique trypanosome components are the cause of this suppression or if it results from massive antigenic overstimulation. T-cell suppression is thought to result from the development of immunosuppressive macrophages responding to the combined effects of trypanosome products and interferon-γ with production of immunosuppressive levels of nitric oxide and prostaglandins. In this regard, *T. brucei* have been shown to directly stimulate murine T cells to produce interferon-γ. Trypanosomes have also been recently shown to have an endogenous prostaglandin F(2alpha) synthase and generation of this prostaglandin by the parasites may contribute to host pathology (Kubata et al. 2000).

In addition to the microscopic pathology and the immunopathology that the infection induces, there are extensive changes in host physiology in persons with trypanosomiasis. For example, the reproductive capacity of infected individuals is low. Low estradiol levels are reported to occur in 65 percent of infected females and low testosterone levels in 50 percent of infected males (Ikede et al. 1988; Boersma et al. 1989; Soudan et al. 1993). Abnormalities in thyroid hormones have also been observed (Reincke et al. 1993). These observations suggest that all organ systems and physiological functions are affected by the infection. A summary of some of the physiological changes that occur in people with African trypanosomiasis is shown in Table 2.

Trypanosomiasis-resistant hosts

Several African wildlife species are found throughout areas where trypanosomiasis is endemic. These animals were presumably selected by co-evolution with trypanosomes and tsetse flies to have developed methods to limit the growth of African trypanosomes and the severity of trypanosome-induced pathology. The little information available on mechanisms of resistance expressed by these animals was made possible by the pioneering work of Jan Grootenhuis, a Dutch veterinarian who established a breeding herd of Cape buffalo and eland in Nairobi, Kenya, outside of the tsetse habitat. There, several generations of the wild bovids were raised in the complete absence of trypanosomiasis. Experimental challenge with trypanosome-infected tsetse flies and needle inoculation with cloned bloodstream-form organisms showed that the bovids could be infected but showed few or no signs of disease. In both cases, only one or a few waves of parasitemia developed after which infections became cryptic being characterized by the presence of between one and ten mammal-infective trypanosome(s) per ml blood. (Reduth et al. 1994). Eventually, the infections were cleared. During the period of cryptic parasitemia, the wild bovids could not be super-infected with different trypanosome isolates.

Infected Cape buffalo were shown to develop broad-acting trypanocidal activity in their blood plasma. This was mediated by production of a trypanocidal concentration of hydrogen peroxide as a result of catabolism of endogenous plasma purine by plasma xanthine oxidase (reviewed in Wang et al. 2002), and was contingent on an infection-induced decline in blood catalase (Wang et al. 1999). However, the change in blood chemistry was not responsible for the long-term suppression of parasitemia in the infected Cape buffalo. By a month after infection, blood catalase was restored to preinfection levels but parasitemia remained cryptic (Wang et al. 2002) Consequently, a second mchanism must be responsible for control of parasite population growth at this time. Possible mechanisms include the development of trypanosome growth-inhibitory antibodies directed against conserved receptors for required macromolecules, and the priming of a cell type that can accelerate the development of antibodies specific for trypanosome VSG thus limiting population growth in a VSG-specific manner.

DIAGNOSIS

A primary consideration for diagnosis of African trypanosomiasis should be a history of travel or residence of the patient in an area of Africa where the disease occurs. This said, diagnosis of African trypanosomiasis depends on the microscopic demonstration of trypanosomes in the blood, in lymph node aspirates or in cerebrospinal fluid. The very elevated macroglobulinemia that occurs in patients has been considered diagnostic of African trypanosomiasis but it is only suggestive as other diseases such as leishmaniasis also cause a macroglobulinemia.

Unfortunately, the clinical features of the disease are not sufficiently unique to be diagnostic, except possibly during the late sleeping sickness stage; the number of parasites in the blood and other body fluids is often very low, making detection difficult. Multiple sampling and concentration techniques are often required to find the parasites. In *T. b. gambiense*-infected people in particular, the parasitemias can be extremely low and make infection with this trypanosome particularly difficult to diagnose (DeRaadt and Seed 1977). It should be noted that there have been attempts to develop a list of symptoms (enlarged lymph nodes, CNS-associated signs, etc.) that are common to sleeping sickness patients, which could be used by rural health personnel to make a tentative diagnosis of a *T. b. rhodesiense* infection (Boatin et al. 1986).

Examination of stained thin or thick blood films for trypanosomes is still a good diagnostic technique, and repeated daily examination can increase the probability of detecting the parasite. The use of concentration methods such as miniature anion exchange columns (Lanham and Godfrey 1970; Lumsden et al. 1979, 1981),

or hematocrit tube centrifugation (Woo 1971; WHO 1986; Woo and Hauck 1987; Levine et al. 1989) coupled with microscopic examination can increase the sensitivity of methods for detection of trypanosomes several fold. A modification of the hematocrit tube centrifugation test is the acridine orange quantitative buffy coat (QBC) technique (Bailey and Smith 1992). This test is simple, quick, and sensitive. Since it detects trypanosomes microscopically, it does not produce false positives. The concentration techniques have been modified for use in field surveys, but they are still difficult to use in field settings because of the need for a centrifuge and electrical power (WHO 1986).

If trypanosomes cannot be detected in the blood of a suspected trypanosomiasis patient, the microscopic examination of a wet preparation from an enlarged cervical lymph node may confirm the diagnosis. Once the trypanosomes are detected in the blood and lymph fluids, the CSF must also be examined in order to determine the stage of the disease. Distinguishing between the acute blood stage of the infection and the later chronic neurologic stage is important in determining the appropriate chemotherapeutic regime. Centrifuged sediments of the CSF should be examined for trypanosomes. The fluid should also be examined to determine if there are elevated white cell counts and increases in protein concentration (DeRaadt and Seed 1977). Both CSF and blood from patients should be examined periodically after completion of chemotherapy in order to ensure that the patient is cured.

The use of in vitro cultivation of trypanosomes or the inoculation of suspected samples into experimental animals is not currently practical for routine diagnosis, although both procedures are used extensively for research purposes. A kit for in vitro isolation (KIVI) of trypanosomes from sleeping sickness patients in the field has been developed (Aerts et al. 1992; Truc et al. 1992). This test is of value in isolating trypanosomes from infected individuals; however, because KIVI requires days for the cultures to produce detectable numbers of trypanosomes, it will probably have limited diagnostic value. Its main importance will be as a standard for evaluating other quicker diagnostic tests.

Immunodiagnostic tests can be especially useful for mass field surveys and for other epidemiological investigations as well as for the detection of latent infections. A number of serological tests have been developed and many are currently being tested in the field. Immunofluorescence, complement fixation test, and card agglutination test for trypanosomes (CATT) have all been utilized in epidemiological studies. Several of these procedures are available in the form of commercial kits for field use. These tests are based on the detection of antibody in the sera of infected individuals and utilize antigens from blood-stage trypanosomes. For example, the CATT test employs a fixed, stained suspension of intact trypanosomes containing a mixture of various antigenic types. The various types selected are based on the frequency with which they appear in the human population in a broad geographic area. This test is easy to perform, inexpensive, and convenient for field work. However, like many indirect diagnostic tests, it is not perfect. For example, it is not equally effective in all geographic areas, nor is it equally effective for detection of the two forms of human trypanosomiasis. This test is also reported to give positive reactions with antibodies to species of trypanosomes infecting animals but not humans (Penchenier et al. 1991).

Tests that use monoclonal antibodies to detect trypanosome antigens in serum are now being developed (Komba et al. 1992; Nantulya et al. 1992). Antigen detection tests would be valuable since they are based on detection of trypanosome antigens in the blood and, therefore, on active infection. Tests that detect antibody cannot distinguish between a past and a present infection, but those that detect antigen can. The antigens produced by modern biotechnology have not yet been used for diagnostic purposes. Although molecular probes have been used successfully in epidemiological studies, hybridization and polymerase chain reaction (PCR) technologies are not currently used for routine diagnosis because tests based on them are still too slow and cumbersome.

In a recent comparison of the CATT, the hematocrit centrifuge tube assay, the minianion exchange column technique, the QBC, the KIVI, and the thick blood film (TBF) procedure, the TBF was found to be as sensitive as any of the others. It also has the advantage of being the simplest and cheapest of all the diagnostic methods. It is rapid and simple, requiring only the staining and examination of the slides (Truc et al. 1994).

EPIDEMIOLOGY AND CONTROL

As mentioned at the start of this chapter, African trypanosomiasis is restricted to Central Africa because of the ecology of the insect vector (*Glossina*, tsetse flies). The tsetse habitat is limited by the Sahara Desert to the north and the cool, dry areas of Southern Africa to the south. The tsetse habitat is approximately the size of the USA, and it is estimated that within this region about 60 million people are at risk. However, this figure is based on a number of suppositions and there is no way to truly know the number of people at risk. A small portion of people in trypanosomiasis endemic areas has been evaluated for the disease and based on this evaluation it is estimated that 300 000–500 000 people presently have sleeping sickness. Of these, only a few will be detected by the screening systems in place and even less will be treated. Sleeping sickness now occurs in 36 countries south of the Sahara and there are approximately 200 known disease foci (Kuzoe 1991, 1993).

Epidemiology

The epidemiology of infection caused by *T. b. gambiense* differs from that of infection caused by *T. b. rhodesiense* in many aspects. These include the species of tsetse involved, the type of tsetse habitat, and the number and type of reservoir hosts (Table 1). *T. b. gambiense* is transmitted by flies of the *Glossina palpalis* group, which live primarily in the vegetation along river banks and in moist forests. Tsetse of this group feed frequently on humans in areas where contact is common, such as at river crossings and water holes. There are animals that serve as reservoir hosts of *T. b. gambiense* but people with chronic infection who have relatively mild symptoms provide the major contribution to the persistence of the Gambian type of infection (Jordan 1986; Molyneux and Ashford 1983). *T. b. rhodesiense* is transmitted by tsetse of the *G. morsitans* group. These flies inhabit low woodlands and thickets on lake shores and much of the savanna of Central and East Africa. This group of flies feeds primarily on nonhuman hosts, and humans are only a secondary food source (Seed and Hall 1992). Fishermen, game wardens, and others who enter areas with high tsetse numbers are particularly at risk (Wyatt et al. 1985). In addition, epidemics of the Rhodesian infection occur when there is an increase in tsetse numbers in close association with villages, a development causing an increase in fly–human contact. The areas in which the West African infection occurs overlap the areas of infection caused by *T. b. rhodesiense* in countries such as Zaire and Uganda.

Control

In the past, control of trypanosomiasis was partly based on the removal of reservoir hosts from areas near human settlements. This involved the fencing out and killing of game animals. Other early attempts at control of trypanosomiasis involved the destruction of tsetse habitats. Both the elimination of reservoir hosts and the destruction of tsetse habitats are now considered ecologically unsound. In addition, game animals are a tourist attraction and consequently an important source of revenue for African countries with managed National Parks and Safari operations including lodges.

The epidemiology of human African trypanosomiasis is shaped by many factors (Table 3). They include the type and density of the vector, the type and density of the reservoir host population, and the density of the human population. The densities of the fly population and of the host population are dependent on environmental conditions such as temperature, humidity, water availability, and other factors of the habitat. It is a general truth that any condition that increases the contact between tsetse, the reservoir hosts, and humans, including growth of population, will increase the risk of human infection. The chronic nature of the infection in both the vector and mammalian host makes continued surveillance and treatment of the human population, and vector control necessities if low prevalence rates are to be maintained in the human population. Current control of human African trypanosomiasis is therefore based on three arms (Seed 2000). The first is the continued surveillance in individuals by mobile field teams for the detection of trypanosomiasis. It is believed that every individual in an endemic area should be screened at least once a year. The second arm of a control program is the treatment of the infected individuals. These two phases are essential for a successful control program because African trypanosomiasis is a chronic disease and ambulatory individuals can act as reservoirs of the infection. This is especially important for the West African

Table 3 *Some factors involved in the epidemiology of African trypanosomiasis of humans* [a]

Fly	Mammal	Environmental	Parasite

	Intercurrent infections		

a) From Molyneux et al. (1984), Jordan (1986), Seed and Hall (1992), Vale (1993)

form of the infection. Since East African trypanosomiasis is a zoonotic disease, the treatment of infected individuals has less effect on the incidence of human infections. In East Africa, cattle are an important reservoir of the disease. It has been shown that cattle infected with *T. b. rhodesiense* and their movement can significantly contribute to the epidemiology of the human infection especially in the vicinity of cattle markets. It has, therefore, been suggested that the surveillance of cattle for human-infective *T. b. rhodesiense* and the targeted treatment of these cattle would be an important addition to the control of sleeping sickness (Hutchinson et al. 2003). The third arm of current control programs involves vector control.

All species of *Glossina* are blood feeders and as adults are totally dependent on this food source. The different species of *Glossina* have different host preferences, and both sexes take bloodmeals. In addition, tsetse are larviparous and a female produces only 8–12 larvae during her limited life span of 3–5 months. The larvae are deposited on the ground and immediately burrow into patches of moist soil or sand such as occur in shaded areas under fallen logs, rocks or bushes. The need for frequent bloodmeals and the reproduction dynamics of tsetse are important factors in shaping the epidemiology of trypanosomiasis (Molyneux and Ashford 1983).

The environmental requirements of the flies and their low reproductive rates make then vulnerable to control by a variety of techniques. The techniques used are based on our knowledge of tsetse behavior and other aspects of epidemiology of trypanosomiasis. Control programs using insecticide application and traps are in wide use. Traps and insecticides such as the chlorinated hydrocarbons and synthetic pyrethroids, when properly used, cause limited environmental damage (Molyneux and Ashford 1983; Jordan 1986). Depending on the environmental conditions, application may be by spraying with individually carried sprayers or from aircraft. The latter technique is used when broad coverage is needed. Technical factors that are considered important for achieving good results in spraying programs include appropriate formulation of the spray to obtain proper droplet size and the proper selection of insecticide. Either a residual or a nonresidual insecticide may be selected, depending on the retention time desired. Selection of appropriate sites for spraying is also important. Many of the requirements for successful use of insecticides for control of tsetse are reviewed by Jordan (1986) and Molyneux and Ashford (1983). Although control by insecticide application is effective, it is also expensive and repeated application is required if results are to last.

The use of fly traps and screens or rags impregnated with insecticides is more economical than environmental spraying and has been demonstrated to lower tsetse numbers dramatically in limited areas (Molyneux and Ashford 1983; Jordan 1986; Vale 1993). The biconical trap (Figure 9) has been shown to be effective in reducing tsetse numbers in West Africa. Detailed knowledge of fly behavior in the area where control is attempted is required for proper design and placement of traps and screens.

There are chemicals to which tsetse are known to be attracted. These include carbon dioxide and volatile compounds in the breath and urine of cattle (Vale and Hall 1985a, b; Vale et al. 1988). Some of these compounds have been identified: they include acetone, 1-octenol-3-ol, and the phenolic compounds 4-methylphenol and 3-n-propylphenol. The baiting of traps with these synthetic compounds and with carbon dioxide has been shown to increase the numbers of flies caught. There are also substances from humans that are repellent to some tsetse (Vale 1993), and these must not be permitted to contaminate traps. In addition, color and design of traps or screens are important factors in attracting and inducing the landing of flies. In the Congo Republic, a modified biconical trap is used for the control of tsetse in areas where trypanosomiasis occurs (Lancien 1981). The traps are relatively inexpensive and can be constructed and maintained by the villagers themselves if the necessary materials are provided (Okoth 1986).

In Zambia, disposable screens impregnated with insecticide have replaced traps (Figure 9b). The screens are 2×1 m and have a central black area of 1×1 m surrounded by two 0.5×1 m rectangular blue areas. The screens are supported by wooden frames that can be stuck into the ground. The insecticide used, Deltamethrin, persists on the screens for months (Vale 1993). The screens are inexpensive, require no maintenance, and can be utilized with or without the use of chemoattractive odors (Vale 1993). These screens are extremely effective in killing tsetse and in some areas are believed to have reduced or even eradicated tsetse populations. Similar screens have been used to control *G. pallidipes* in Kenya (Opiyo et al. 1990). The use of traps and screens in the control of tsetse has been extensively discussed by Jordan (1986), Laveissiere et al. (1990), and Vale (1993). They hold great promise for future control of tsetse populations and, therefore, African trypanosomiasis in an environmentally friendly way. However, although both traps and disposable screens have been successfully used, they require continued maintenance and replacement due to environmental damage, theft, and animal damage. They are not cost-free and require a strong infrastructure for maintenance.

An approach related to the use of screens and traps in tsetse control has been the use of cattle dipped in insecticide, or on which insecticides have been poured or sprayed. This technique has been shown to lower tsetse numbers (Fox et al. 1993). This procedure is relatively inexpensive and has the additional advantage that it also reduces the populations of ticks and other biting insects.

There have been attempts to control tsetse by the release of sterile flies. *Glossina austeni* was successfully

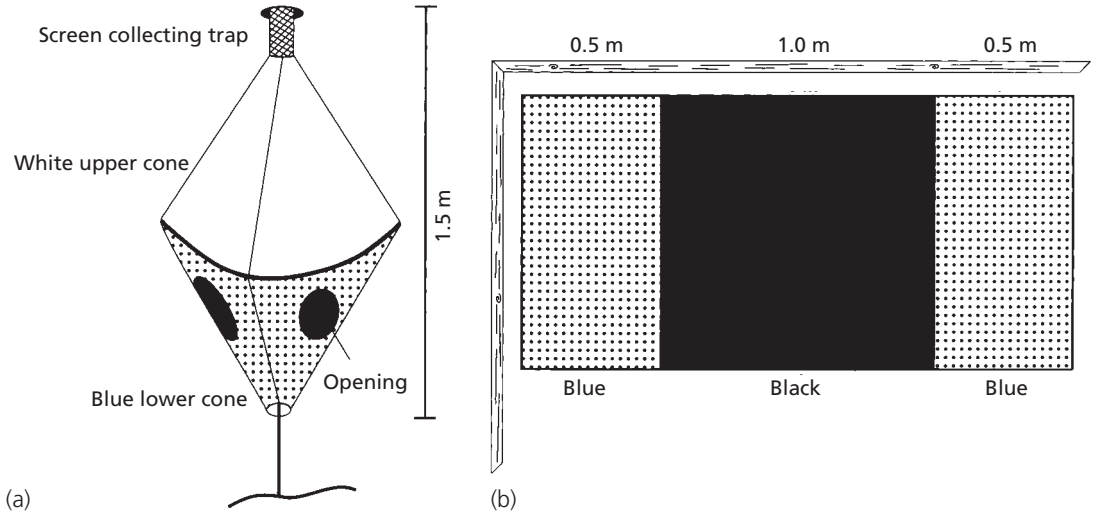

Figure 9 (a) *Biconical tsetse trap and* **(b)** *insecticide impregnated screen or target.*

eradicated from the Island of Zanzibar (Vreysen et al. 2000). Based on this success are programs currently being initiated to attempt to eradicate tsetse using sterile fly technology in combination with other control activities. However, there is considerable debate as to the validity of this approach because of the high cost required to eliminate tsetse from Zanzibar (Molyneux 2001). In addition, the fact that Zanzibar is a small, isolated island that tsetse cannot reinvade has suggested that Zanzibar is not a satisfactory model for the tsetse–African trypanosomiasis situation in mainland Africa (Rogers and Randolph 2002). There have also been attempts to find tsetse pathogens, and to identify pheromones for use in programs to reduce fly populations (Molyneux and Ashford 1983; Langley et al. 1988). An approach using biotechnology to develop a transmissible vector that would cause male sterility has been proposed, as has an approach to control tsetse fly susceptibility to infection that is based on the release of antitrypanosome peptides by symbiotic prokaryotes (reviewed by Aksoy 2001; Aksoy et al. 2002). However, although this is promising, control based on these techniques has not reached a stage of development sufficiently advanced to even permit testing.

The lack of economic resources is a major factor limiting effective control of trypanosomiasis. In many of the endemic countries, the per capita gross national product is less than US$500, and there may be an expenditure of less than US$10 per individual for total health care. Several years ago, the cost of surveillance alone was estimated at approximately US$1 per individual at risk, and the cost of treatment at US$35 per patient in the early stage and US$135 per patient in the late stage of disease. These costs are likely to have increased. In addition, there are costs for vector surveillance and control (Kuzoe 1991; WHO 1986). It is obvious that the necessary resources for control of sleeping sickness are very limited in most areas of Africa, and any change in government priorities, e.g. to control political unrest, will decrease the amount of money available for long-term control activities. Civil unrest also disrupts the flow of external aid required to supplement local funds for control activities.

CHEMOTHERAPY

Chemotherapeutic treatment of African trypanosomiasis is important in reducing the incidence of the infection especially in the West African form of the disease. However, surveillance and early detection of both forms of the disease are essential because the treatment protocol is shorter for patients in the early stages of the disease and drug-induced morbidity and mortality are lower than in patients in the late stages of the disease. Cure rates are also higher when infected individuals are treated early in the disease rather than during the late secondary stages. Control of both forms of sleeping sickness, therefore, works best if early detection and treatment are used together.

Suramin is used to treat patients with primary stage infections that do not involve the CNS. This drug is effective against both the Gambian and Rhodesian form of the disease but because it does not cross the blood–brain barrier, it is not effective against the secondary CNS stages. Suramin is a polysulfonated naphthylamine derivative of trypan red and was first found to have trypanolytic activity by Ehrlich. It is relatively toxic and may cause optic atrophy, blindness, nephrotoxicity, and adrenal insufficiency in some patients (Pepin and Milord 1994). Its exact mode of action is not known, although it inhibits a wide variety of trypanosome enzymes including glycolytic enzymes and the mitochondrial glycerol phosphate oxidase enzymes.

Pentamidine isethionate and other aromatic diamidines were first examined for trypanocidal activity in the 1930s. Like suramin, the dicationic pentamidine isethionate does not cross the blood–brain barrier, and is therefore used in patients with CNS involvement only to clear the blood of trypanosomes prior to treatment with melarsoprol. Pentamidine isethionate may produce nephrotoxicity, hepatotoxicity, and pancreatic toxicity in some patients (Sands et al. 1985; WHO 1986; Goa and Campoli-Richards 1987; Kapusnik and Mills 1988; Pepin and Milord 1994). The exact mode of action of this drug is unknown, but the strongly basic dicationic molecule binds to many cellular components, including a variety of trypanosome enzymes, causing their inhibition. It also binds to DNA, preferentially to adenosine–thymidine-rich regions in the minor groove. It has recently been shown that pentamidine isethionate is actively metabolized by the mammalian cytochrome P450 drug-metabolizing system (Berger et al. 1990).

In contrast to suramin and pentamidine isethionate, melarsoprol does cross the blood–brain barrier and is used to treat patients in the late secondary CNS stages of trypanosomiasis. Until very recently, melarsoprol has been the only drug available for treatment in this stage of the disease. Melarsoprol failures have been reported in several areas of sub-Saharan Africa, where sleeping sickness cases have a high prevalence. At this stage, it is unclear whether the treatment failures are a result of drug metabolism by the patient, or development of resistance in the parasites, or both. melarsoprol is an organic arsenical, first developed by Friedheim (1949). As with pentamidine isethionate and suramin, its exact mechanism of action is unknown, although it has been shown to inhibit a variety of trypanosome enzymes and functions in vitro. It is toxic, and in 1–10 percent of treated patients there is encephalopathy with mortality rates of 1–5 percent. Other adverse side-effects include fever, headache, joint pain, gastrointestinal disturbances, renal damage, and hypertension (Pepin and Milord 1994; WHO 1986). As noted above (see Trypanosomiasis-susceptible hosts) the encephalopathy may have an immunological basis (Jennings et al. 1989). It has been possible to reduce the development of meningoencephalitis and perivascular cuffing in infected mice by treatment with the immunosuppressive drug azathioprine (Jennings et al. 1989).

Suramin, pentamidine isethionate, and melarsoprol are still the primary drugs used to treat patients with African trypanosomiasis. The only new drug that has been developed is difluoromethylornithine (DFMO), also known as eflornithine and Ornidyl) a specific inhibitor of ornithine decarboxylase, which is the first enzyme in the polyamine biosynthetic pathway (Bacchi and McCann 1987). Currently, it is the only drug other than melarsoprol available for treatment of late-stage trypanosomiasis (Schechter et al. 1987). In the trypanosomes, exposure to DFMO leads to rapid depletion of putrescine and to low spermidine levels. It induces transformation of the replicating long slender form to the nonreplicating short stumpy form and, therefore, causes an inhibition of trypanosome growth. DFMO is relatively non-toxic but adverse reactions can include anemia, thrombocytopenia, and gastrointestinal disturbances, all of which are reversible. It is an extremely valuable chemotherapeutic agent for the treatment of late-stage patients who do not respond to melarsoprol. *T. b. gambiense* seems to be more susceptible to DFMO than is *T. b. rhodesiense*, although the reason for this difference is not clear (Bacchi et al. 1990).

Because DFMO is a specific inhibitor of ornithine decarboxylase with no other known inhibitory activity, rapid selection for drug-resistant trypanosomes has been possible in experimental studies. Resistance has also been observed in trypanosomes isolated from humans treated with DFMO. Considerable research is being conducted in an effort to find other compounds that inhibit the polyamine pathway. Treatments using combinations of drugs are also being investigated in an effort to decrease the probability of selecting for drug resistance.

The current treatment regime recommended by the WHO for reducing parasitemia in patients with *T. b. gambiense* infection is the use of pentamidine isethionate or, where there is resistance to this drug, with suramin. This is done in patients in both early (or primary) and late (or secondary) stages of the disease. In the patients in the late stages of the disease who have CNS involvement, this treatment is followed by treating with multiple injections of melarsoprol. The treatment of patients in the early stages of a *T. b. rhodesiense* infection is with suramin. In patients with the late stages of a *T. b. rhodesiense* infection, suramin is used to clear the blood and lymph and then multiple injections of melarsoprol are given (WHO 1986). The details of the treatment regimes are outlined in Table 4 (WHO 1986).

Currently, the number of drugs available for the treatment of African trypanosomiasis is limited and all except DFMO are quite toxic to humans. Researchers are currently searching for better analogues of existing drugs, investigating the use of drugs in combinations, and trying to develop compounds that inhibit biochemical pathways unique to trypanosomes. Although there are new leads in this field, further research is critically required.

VACCINATION

Because of the phenomenon of antigenic variation no vaccine is available.

CONCLUSION

Control of trypanosomiasis is possible, but it requires continuous surveillance of the human population and

the treatment of all infected individuals. It also requires control of tsetse flies through the use of traps and insecticide-impregnated screens and the judicious application of insecticides to the environment. It is possible that in the future insecticides will be required only in limited circumstances. The application of any control measure is currently limited in many areas of Africa owing to political instability as well as the lack of resources to initiate and maintain them adequately (Williams et al. 1993). While an enormous amount of information on trypanosome cellular and molecular biology and host immune responses has been gathered using modern research approaches and tools, this knowledge has not yet, with the exception of the introduction of DFMO for chemotherapy, resulted in new or improved methods to control trypanosomiasis. However, the discovery that lysis of *T. b. brucei* by human serum is due to the presence of apolipoprotein L-1 (Vanhamme et al. 2003), and the likelihood that this protein is also responsible for the lysis of *T. congolense* and *T. vivax* in human serum, may result in translational research leading to novel prophylactic regimes against nagana and therapeutic regimes against *T. b. rhodesiense*-sleeping sickness.

INTRODUCTION

In 1907, the Brazilian scientist Carlos Chagas left the city of Rio de Janeiro to work as a malaria control officer at Lassance in the state of Minas Gerais. Chagas noted that poor houses in the area were infested by a large blood-sucking insect, the triatomine bug (Hemiptera, Reduviidae) (Figure 1). He was aware that blood-sucking insects transmitted human diseases such as malaria and immediately suspected that triatomine bugs might also carry infectious agents. He examined bug feces and found a flagellated protozoan parasite. At the Manguinhos Institute in Rio de Janeiro, marmosets exposed to infected bugs developed blood parasitemias of a new trypanosome, which Chagas named *Trypanosoma cruzi* after his mentor Oswaldo Cruz.

Back in Lassance, *T. cruzi* was found in the blood of sick children living in bug-infested houses (Figure 2). Chagas and his distinguished colleagues from what is now the Instituto Oswaldo Cruz, went on to describe clinical aspects of the disease, the life cycle, experimental animal models, and to discover natural mammalian hosts such as the armadillo. These discoveries were remarkable, not least because *T. cruzi* was found first in its insect vector. Chagas' early work was initially controversial, and it was not until some years later that the public health importance of Chagas disease became apparent when scientists in other Latin American countries reported its widespread distribution. The true route of transmission, through contamination with infected bug feces, was conclusively demonstrated in 1912 by Emile Brumpt. The history of the discovery and early investigations of Chagas disease is described by Miles (1996, 2004) and Lewinsohn (2003).

Chagas disease, for those who survive the acute phase of infection, primarily affects the heart and alimentary tract. Its pathogenesis remains enigmatic in that many infected people remain healthy for life and the precise reasons for a poor prognosis are not fully understood. There has been an intense expansion of interest in *T. cruzi*, driven largely by a desire to understand the disease process, how the organism survives for life in the infected mammalian host, and the unique features of trypanosome molecular biology. *T. cruzi* is also now known to be an opportunistic infection: in addition to being transmissible by blood and organ donors, it also relapses in immunocompromised individuals. South American trypanosomiasis is predominantly a disease of poverty. As such it is amenable to control by public health interventions to manage the insect vectors, supplemented by measures to eliminate transmission by blood transfusion.

T. cruzi is one of many trypanosome species in the New World, but only one other species is known to infect humans. Like *T. cruzi*, *Trypanosoma rangeli* was first found in triatomine bugs and later in children, but it is not considered to be pathogenic and its medical importance lies in the need to distinguish *T. cruzi* and *T. rangeli* infections during diagnosis, by isolation of the

Figure 1 *An adult female triatomine bug (*Panstrongylus megistus*) (Courtesy of T.V. Barrett)*

parasite. Unlike *T. cruzi*, *T. rangeli* is transmitted by the bite of the vector, through infection of the triatomine bug salivary glands.

Hoare's classic monograph (1972) still contains an excellent introduction to the New World human trypanosomiases; Tyler and Miles (2003) gives a recent review on research and WHO (2002) and Maudlin et al. (2004) provide texts on clinical aspects, diagnosis, and disease control.

Figure 2 *Carlos Chagas with one of the first discovered infant cases of* Trypanosoma cruzi *infection*

CLASSIFICATION

T. cruzi is a kinetoplastid protozoan parasite in the family Trypanosomatidae, which includes the disease agents of both the leishmaniases and the trypanosomiases. The genus *Trypanosoma* includes two species responsible for major public health problems in South America and Africa (*T. cruzi* and *Trypanosoma brucei*, respectively) and others that are not pathogenic (e.g. *T. rangeli*). *T. cruzi* falls into the section Stercoraria (as distinct from the section Salivaria of *T. brucei*; see African trypanosomiasis). The Stercoraria are characterized as trypomastigotes with a free flagellum, a large kinetoplast that is not terminal, pointed posterior end, discontinuous reproduction in the mammalian host and contaminative transmission (except *T. rangeli*) and nonpathogenic (except *T. cruzi*). The stercorarian trypanosomes, with the notable exception of *T. rangeli*, are transmitted from the vector by contamination with the insect's feces. Reproduction in the mammalian host is typically discontinuous – that is, it is confined to particular life cycle stages or tissue sites. *T. cruzi* is the type species of the subgenus *Schizotrypanum*, an assemblage of morphologically indistinguishable species parasitic in diverse mammals, mostly restricted to New World and comprising *T. cruzi* plus *T. cruzi*-like organisms in the Americas, and a number of cosmopolitan bat trypanosomes. The subgenus *Schizotrypanum* is characterized by trypomastigotes that are small, typically C-shaped with a large kinetoplast near the short, pointed posterior end, and have intracellular reproduction as amastigotes in the mammalian host.

As described below, chemical taxonomic methods, especially phenotypic comparisons by isoenzyme electrophoresis and, more recently, comparative DNA analyses, have demonstrated a remarkable diversity within the *T. cruzi* species and the existence of at least two principal subdivisions named *T. cruzi* I and *T. cruzi* II (Campbell et al. 2004).

STRUCTURE AND LIFE CYCLE

T. cruzi is a eukaryote with a nucleus; it has chromosomes that do not condense during cell division and can only be resolved by electrophoretic methods devised to separate large molecules of DNA. Extranuclear DNA is present in the form of a discrete, visible organelle, the kinetoplast, containing minicircle and maxicircle DNA and associated with a large single-branched cristate mitochondrion. The kinetoplast lies adjacent to a basal body and flagellar pocket from which a flagellum emerges (except in the amastigote stage of the life cycle) having nine peripheral pairs of microtubules, a central doublet and a parallel paraxial rod. The flagellum runs alongside the main body of the organism, in a posterior-to-anterior direction, and adhering to it to

form an undulating membrane leading to an anterior free flagellum. Interior organelles include an endoplasmic reticulum and a Golgi apparatus, and a specialized glycolytic organelle (the glycosome). The organism is bound by a complex network of subpellicular microtubules. Hoare (1972) gives ranges of dimensions for proven *T. cruzi* trypanosomes from humans as: length 11.7–30.4 μm; free flagellum 2.0–11.2 μm; breadth 0.7–5.9 μm. Further details of structure can be found in elegant electron microscopical studies of *T. brucei*, with which *T. cruzi* shares many features, and supplementary studies of *T. cruzi* (Tetley and Vickerman 1991).

There are three principal stages in the *T. cruzi* life cycle. The amastigote stage multiplies within nonphagocytic and phagocytic cells by binary fission. The epimastigotes, which have a kinetoplast adjacent to the nucleus and an undulating membrane that runs along approximately the anterior half of the organism, divide by binary fission in the hindgut of the triatomine bug vector. Trypomastigotes, with the kinetoplast at the posterior end, do not divide and are the forms found circulating in the blood of the mammalian host. Trypomastigotes are also the infective (metacyclic) stage that occurs in the rectum of the vector and in bug feces deposited during feeding. There are, therefore, some similarities between the life cycle stages of *T. cruzi* and those of both *Leishmania* and *T. brucei* in that *Leishmania* also has amastigotes that divide intracellularly (see Old World leishmaniasis and 17, New World leishmaniasis) and *T. brucei* has circulating trypanosomes but, in contrast to *T. cruzi*, the latter divide in the blood by binary fission (see African trypanosomiasis).

The life cycle is summarized in Figure 3. Metacyclic trypomastigotes deposited on the mammalian host in bug feces have the capacity to penetrate abraded skin or the wound made by the bite of the bug. They can also cross the oral and nasal mucosae, or the conjunctiva if bug feces get into the eye. These metacyclic forms are

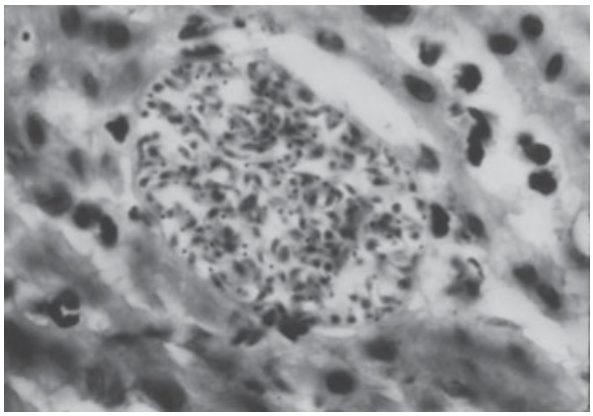

Figure 4 *Pseudocyst of* Trypanosoma cruzi *in umbilical cord (Courtesy of Dr Hipolito de Almeida)*

slender, highly motile organisms, which often rapidly traverse the field of view when seen by light microscopy. Once inside the mammalian host, they can penetrate phagocytic or nonphagocytic cells to form a local cutaneous or ocular lesion. Within the cell, the vacuole containing the *T. cruzi* trypomastigote fuses with lysosomes to form a phagolysosome, from which the organism then escapes to lie free in the cytosol. The trypomastigote transforms to an amastigote which divides by binary fission forming a pseudocyst (false cyst), so called because it has no true cyst wall but is simply bounded by the membrane of the host cell. About 5 days later, there may be up to 500 amastigotes transforming to small motile C-shaped trypomastigotes within the pseudocyst (Figure 4). The trypomastigotes are released into the surrounding tissue, either to infect other cells and repeat the intracellular cycle or to circulate in the blood (Figure 5). When the pseudocyst ruptures, not all the amastigote forms may have transformed to trypomastigotes. Amastigotes released when the cell bursts are thought to be destroyed locally but are occasionally found circulating in the blood of mice with fulminating experimental infections.

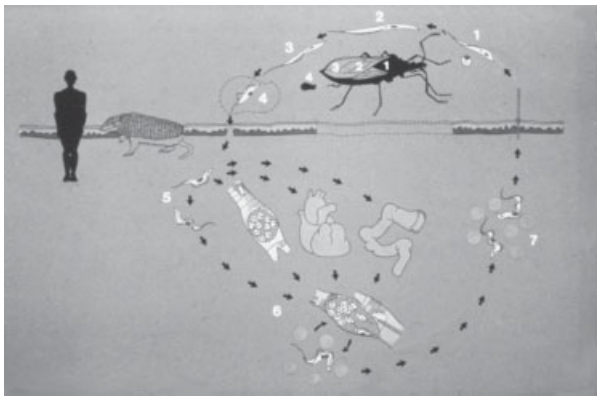

Figure 3 *A summary of the life cycle of* Trypanosoma cruzi *(see text) (Courtesy of Meddia)*

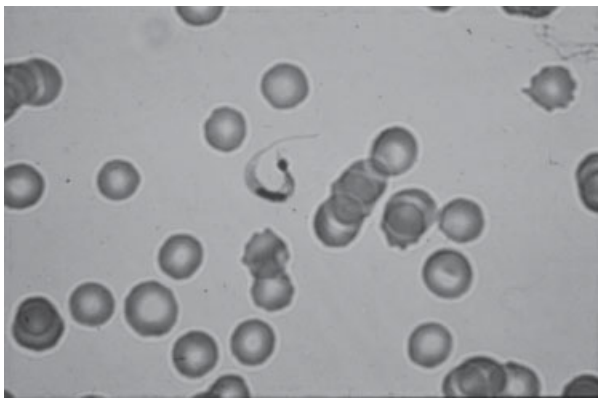

Figure 5 Trypanosoma cruzi*: C-shaped trypomastigote in circulating blood (see text)*

Two types of transformation from amastigote to trypomastigote have been described within the pseudocyst. The first, fusiform transformation, involves elongation of the body and migration of the kinetoplast. The second, orbicular cycle transformation is by unrolling of sphaeromastigotes (flagellated amastigote forms with a flagellum that encircles the body without producing an undulating membrane) that have a central vacuole: this orbicular transformation may, however, be an artefact of dry fixation and staining of tissue smears (Hoare 1972).

The released trypomastigotes do not all have the same morphology and behavior. There are two types: slender highly motile trypomastigotes, reminiscent of the infective metacyclic forms found in bug feces, and smaller, broader less motile forms. The slender forms tend to traverse the field rapidly when seen microscopically, whereas the broader forms, although motile, remain for a longer time in the same field of view. The slender motile form has an elongated nucleus, a subterminal kinetoplast and a short free flagellum, whereas the broad form has an oval nucleus, almost terminal kinetoplast and a long free flagellum. The slender forms are generally only seen in the blood of experimental animals, such as mice, during initial acute or fulminating infections (Risso et al. 2004). It has been proposed, although not proven, that the slender forms are pre-adapted to penetrating cells and renewing the intracellular cycle, whereas the shorter, broader forms may persist in the blood to be taken up by the vector with the bloodmeal. Unlike *T. brucei*, however, both slender and broad forms are thought to have active mitochondria (in *T. brucei* dividing slender forms depend on glycolysis and the mitochondria are only fully active in the stumpy forms, to prepare them for life in the tsetse fly).

Except in experimental models with *T. cruzi* strains that are highly virulent to mice, the number of circulating trypomastigotes in the blood is generally quite low (less than one per field at $\times$400 magnification in a fresh blood film) and the blood parasitemia rapidly becomes subpatent to microscopy. Low levels of circulating organisms, which may remain for the life of the host, can then be detected only by more sensitive methods.

The development of *T. cruzi* in the triatomine bug is confined to the alimentary tract. Bugs acquire infection by feeding on an infected mammalian host (or rarely by cannibalizing other recently fed bugs) and there is no transovarial transmission from adult female to egg. Once infected, triatomine bugs retain infection throughout the molting cycles. The development of *T. cruzi* in the vector, dependent on the stage of the insect, in general takes around 10–15 days. Trypomastigotes in the bloodmeal transform to amastigotes and sphaeromastigotes in the foregut, and multiply by binary fission. In the midgut, division is by binary fission in the epimastigote stage. In the rectum, epimastigotes attach to the epithelium and transformation to metacyclic trypomastigotes begins. More detailed descriptions of the life-cycle stages can be found in Hoare (1972) and Brack (1968).

Contamination with infected bug feces during or just after the bloodmeal is not the only route of transmission. Blood transfusion transmission is commonplace in endemic areas where blood is not screened for the presence of *T. cruzi* antibodies or not pretreated with gentian violet (WHO 2002). All blood donors who have resided in endemic areas and been exposed to triatomine bugs should be screened for antibodies, as should all organ donors or organ recipients with relevant histories. Antibody testing of blood donors is mandatory in some countries. It has been shown experimentally that transmission may also occur by the oral route, by consumption either of triatomine bugs or of food contaminated with bug feces, and possibly by eating uncooked blood and tissues from infected reservoir hosts. Oral transmission may be important in sustaining prevalence rates in insectivorous mammals, particularly those that live in burrows infested with bugs, and several small outbreaks of simultaneous acute cases within families are almost certainly due to oral transmission of *T. cruzi* (see below). Congenital transmission also occurs in a small proportion of children born to seropositive mothers (WHO 2002). Sexual transmission is thought to be extremely rare, as is transmission through the milk from mother to suckling infant. Accidental transmission in the laboratory is not uncommon, usually through inoculation or ingestion. There are no other important insect vectors, although *T. cruzi* may survive in cimicid bugs and produce metacyclic trypomastigotes in the hindgut, which are thought to have given rise to infections in primate colonies, possibly by the oral route. Persistent *T. cruzi* infections may also occur experimentally in ticks (*Ornithodorus moubata*) (Hoare 1972).

All stages of the life cycle of *T. cruzi* are reproducible in culture. Thus, epimastigotes are easily grown on blood agar overlays. A wide range of mammalian cell lines can be infected to produce mature pseudocysts with motile trypomastigotes, which are seen as 'boiling cells' by phase microscopy. Emergent trypomastigotes re-enter cells in vitro such that several intracellular cycles can occur on a single cell monolayer maintained for 20 days or more (Miles 1993).

The life cycle of *T. rangeli* in the arthropod vector is quite distinct from that of *T. cruzi* in that, in bugs belonging to the genus *Rhodnius*, the hemolymph is often invaded, usually more than 40 days after the infective bloodmeal. Salivary gland infections become established in a proportion of bugs that have hemolymph infections. *T. rangeli* is pathogenic to its insect vector and infected bugs may die or not molt successfully. The development of *T. rangeli* in the lumen of the bug gut and in the hemolymph is indistinguishable. Multiplication occurs in the mammalian host but blood parasitemias are scanty. *T. rangeli* is capable of infecting an histiocytic cell line in vitro and surviving as nondividing amastigote-like

forms, but it is not clear whether such intracellular stages contribute to survival in the mammalian host (Eger-Mangrich et al. 2001). The insect vector stages can be grown in vitro. The importance of *T. rangeli* as a human infective agent is secondary, in that it has to be distinguished from *T. cruzi* during diagnostic procedures.

BIOCHEMISTRY, MOLECULAR BIOLOGY, AND GENETICS

Biochemistry

Drug development is often quoted as the incentive for studying the biochemistry of infectious disease agents such as *T. cruzi*. Thus, the absence of some metabolic pathways may make *T. cruzi* vulnerable to drug action that is circumvented by normal mammalian metabolism and, therefore, not toxic to humans. Alternatively, unique features of trypanosome metabolism may expose the organism to drugs that have no equivalent target in humans. An example of absence of a metabolic pathway is the inactive mitochondrion in the blood-stage form of *T. brucei*, mentioned above (and see African trypanosomiasis), although this is not the case for *T. cruzi*. Examples of prominent differences between the biochemistry of trypanosomatids and mammals have been found in purine salvage pathways, trypanothione biosynthesis and catabolism, sterol synthesis, and glycosomal metabolism. Several enzymes are reminiscent of those found in plants, suggesting that such enzymes are prospective drug targets, vulnerable to drugs based on herbicides (Martin and Borst 2003; Wilkinson et al. 2002b). In addition, other unusual features of the molecular biology of trypanosomes have excited great interest among molecular biologists and encouraged their use as model organisms. These include the presence of the kinetoplast and radical editing of mitochondrial mRNA, discontinuous transcription and *trans*-splicing, polycistronic transcription and antigenic variation with epigenetic mechanisms of controlling gene expression.

T. cruzi utilizes sugars, especially glucose, through active transport into the cell; nevertheless, it is not dependent on glucose and can survive by catabolism of amino acids and proteins – there appear to be no major reserve polysaccharides. Glucose catabolism, incomplete even in the presence of oxygen, produces succinic acids and acetic acid; anaerobic catabolism leads mainly to succinate and L-alanine. Enzymes of the glycolytic pathway, all of which have been reported, mostly occur in a specialized organelle, the glycosome, related to the peroxisome, which assists fatty acid metabolism in eukaryotes. The pentose phosphate pathway of glucose catabolism is also present. Amastigote, epimastigote, and trypomastigote stages have almost all enzymes of the tricarboxylic acid cycle (Cazzulo 1994).

Glycosomes lack catalase and oxidases, which regulate hydrogen peroxide in peroxisomes, but contain enzymes for conversion of glucose and glycerol to phosphoglycerate, as well as enzymes for β-oxidation of fatty acids and for ether–lipid biosynthesis; other activities include pyrimidine biosynthesis, purine salvage and carbon dioxide fixation. Enzymes found in the glycosome of *T. cruzi* include hexokinase, phosphoglucose isomerase, phosphofructokinase, aldolase, triosephosphate isomerase, glyceraldehyde 3-phosphate dehydrogenase, glycerol 3-phosphate dehydrogenase, glycerol kinase, malate dehydrogenase, adenylate kinase, and phosphoenolpyruvate carboxykinase; some of these enzymes are also present in the cytosol. Transport of enzymes into the glycosome does not involve larger cytosolic precursors and cleavage of signal sequences. Peptide recognition signals govern importation, as is the case for peroxisomes (Cáceres et al. 2003; Wilkinson et al. 2002a).

Glutathione (GSH) is the thiol of low molecular weight that is largely responsible for protection against free radicals and reactive oxygen in most aerobic organisms. In trypanosomatids, GSH is replaced by trypanothione, a glutathione dimer conjugated to spermidine. In *T. cruzi* glutathione reductase (GR) is largely replaced by trypanothione reductase (TR), which reduces trypanothione disulfide ($T[S]_2$) to dihydrotrypanothione ($T[SH]_2$) with NADPH as cofactor. Substrate utilization of TR is distinct from that of GR but catalytic mechanism is conserved (Wilkinson et al. 2002a). The two negatively charged carboxyl groups on the glycyl termini of the GR substrate, glutathione disulfide (GSSG), are replaced by internal amide groups in $T[S]_2$ and an amino group carrying a positive charge on the spermidine. Also, the two glutathione chains in GSSG can rotate freely about the disulfide bridge whereas the $T[S_2]$ is more rigid due to the linkage by spermidine. There are distinct distributions of hydrophobic and charged residues in GR and TR adjacent to the glycyl regions of the substrate. The R_{37} and R_{347} amino acids of GR, which are thought to bind the carboxyl groups of GSSG, are replaced by tryptophan and alanine (Taylor et al. 1994). The structural consequences of an engineered change in substrate specificity have been resolved by crystallography (Stoll et al. 1997). Studies of trypanothione metabolism in *T. cruzi* have been an interesting model for the development of rational chemotherapy (Bonse et al. 2000). Other aspects of oxidative defense, such as the presence of an ascorbate hemoperoxidase, may be therapeutically exploitable (Wilkinson et al. 2002b).

Parasitic protozoa such as *T. cruzi* rely on the salvage of free purines or re-use of purines from nucleic acids or nucleotides, whereas mammals can synthesize purines de novo. The hypoxanthine analogue allopurinol has been used as an inhibitor of purine salvage but its value as a therapeutic drug is still greatly in doubt (Stoppani 1999).

There has been much research interest in proteinases of *T. cruzi* with the idea that they may be important for invasion of mammalian host cells, and targets for chemotherapy. Cysteine proteinases are the most prominent of the four main groups (aspartic, cysteine, metallo- and serine) in *T. cruzi* although metalloproteinases and serine proteinase are also present (Cazzulo 2002). There may be several other roles for *T. cruzi* proteinases, such as protection against antibody attack, or adaptation to breakdown of the bloodmeal in the insect vector. Proteinase activities can be demonstrated by using electrophoresis in gels with gelatin or fluorogenic peptides as substrates. A 60 kDa cysteine proteinase (cruzipain) resembles cathepsin and papain, and is also known as the GP57/51 antigen, which is recognized by sera from patients infected with *T. cruzi*. The enzyme produces a C-terminal extension domain by self-proteolysis (Alvarez et al. 2002).

Glycosylphosphatidylinositol (GPI) and GPI-related glycolipids are abundant in trypanosomatids. They serve to anchor surface glycoproteins and, although *T. cruzi* does not have the variant surface glycoprotein (VSG) coat characteristic of the African trypanosomes (see African trypanosomiasis), several glycoproteins are bound to the surface of *T. cruzi* by GPI anchors, including the Ssp-4 antigen of amastigotes and the 90 kDa antigen of trypomastigotes. Ferguson and his collaborators have devoted much effort to determining the GPI biosynthetic pathway in African trypanosomes, not only for the intrinsic biochemical interest, but also because this pathway might present a target for trypanosome-specific chemotherapy (Crossman et al. 2002; Lillico et al. 2003).

Another biochemical feature of *T. cruzi*, distinct from the vertebrate host, is the requirement for specific endogenous sterols such as egosterol, rather than cholesterol. This has led to promising new inhibitors of sterol biosynthesis in *T. cruzi* (Urbina 2002; Urbina et al. 2003).

Molecular biology

There is a plethora of recent advances in understanding the basic molecular biology of trypanosomes, fuelled by an international interest in their unusual features and their role as models for other studies. Two molecular processes that have received detailed attention are discontinuous transcription, or *trans*-splicing, and RNA editing of transcripts from the maxicircle mitochondrial genome.

Studies of antigenic variation in African trypanosomes revealed that each primary mRNA transcript was processed by addition of a 39-nucleotide spliced leader sequence transcribed from a separate chromosomal location – the mini-exon genes. The spliced leader is added by *trans*-splicing via Y-shaped intermediates that consist of the 3′-leader precursor linked to the 5′-portion of the main transcript. *Trans*-splicing is assisted by small nuclear RNAs (snRNAs) complexed to proteins, as is intron splicing in higher eukaryotes. *Cis*-splicing introns have also been discovered in *T. cruzi* (Mair et al. 2000). Many trypanosome genes are polycistronic, with transcripts of several genes in tandem on an initial primary transcript. The mini-exon derived RNA (medRNA) is thought to be functionally equivalent to the U1-snRNA present in other eukaryotes. Mature mRNAs of *T. cruzi* are polyadenylated. Pyrimidine (C,T)-rich regions of downstream splice acceptor sites apparently participate in the control of polyadenylation of upstream portions of the primary transcript. This may have a role in gene regulation (Matthews et al. 1994).

For many years, the function of trypanosome kinetoplast minicircles was obscure. It was finally discovered that some mitochondrial maxicircle genes are condensed and that guide RNAs (gRNAs) transcribed from minicircles carry information for editing maxicircle transcripts, by the insertion (and deletion) of uridines. It is not clear why such a complex RNA editing process is required by organisms such as *T. cruzi*, but it may be linked to developmental regulation during movement between host, vector and life cycle stages (Simpson et al. 2003).

Other research on the molecular biology of *T. cruzi* has concerned the cloning of genes encoding products involved in cell invasion or in gene expression during transformation to the infective form (metacyclogenesis), the structural and functional analysis of genes encoding antigens recognized by the host immune response, and cloning portions of the genome identified by probing with heterologous sequences from other organisms.

T. cruzi carries a surface *trans*-sialidase which transfers sialic acid from host components to mucin-like glycoproteins on the surface of the parasite. In this way, *trans*-sialidase is thought to influence adhesion and penetration of host cells and may also have a role in trypomastigote escape from the phagolysosome into the cytoplasm of the host cell (Tan and Andrews 2002; Buschiazzo et al. 2002). There is a large family of putative mucin genes in *T. cruzi*, with hundreds of copies per haploid genome, which share a signal peptide on the N-terminus and a presumed GPI anchoring sequence on the C-terminus, with hypervariable central regions (Argibay et al. 2002; Buscaglia et al. 2004). Mucins isolated from non-infective epimastigote and infective metacyclic trypomastigotes differ in lipid structure. Metacyclogenesis may be induced in the triatomine bug gut by products of hemoglobin digestion: synthetic peptides corresponding to amino acids 30–49 and 35–73 of αD-globin have stimulated differentiation of epimastigotes into metacyclic trypomastigotes (Garcia et al. 1995). There is a large heterogeneous *trans*-sialidase multi-gene family in *T. cruzi* which, among other members, includes genes for *T. cruzi* neuraminidase

(TCNA), shared acute phase antigen (SAPA), and the GP85 surface glycoproteins. The gene family has been classified into four groups. It has been proposed that changes in expression of such multigene families may provide a mechanism by which *T. cruzi* evades the host immune response, analogous to but distinct from antigenic variation in African trypanosomes (Frasch 2003).

A major technological breakthrough in research on the molecular biology of *T. cruzi* has been the development of genetic transformation systems. New plasmid and cosmid shuttle vectors allow *T. cruzi* DNA to be propagated in bacteria and reintroduced into *T. cruzi*, either episomally, or integrated into the nuclear genome by homologous recombination. In this way, *T. cruzi* genes can be deleted or overexpressed so that gene structure and function can be analyzed. Functional complementation of deletion mutants allows portions of the genome encoding a particular function to be identified. RNA inhibition (RNAi) (Lillico et al. 2003) and chromosomal fragmentation provide alternative approaches to identifying gene function although, at the time of writing, RNAi has not yet been achieved for *T. cruzi*. The wide interest in *T. cruzi* molecular biology has led to the establishment of a World Health Organization-sponsored international collaboration to sequence the entire *T. cruzi* genome, which is currently underway (Andersson et al. 1998; Aguero et al. 2000).

Genetic diversity

Early experimental work on *T. cruzi*, its wide range of mammalian hosts, and the large number of triatomine bug vector species suggested that *T. cruzi* might be genetically diverse. *T. cruzi* strains were reported to differ in their virulence and histotropism in experimental animals, in their infectivity to triatomine bug species, in their susceptibility to drug treatment, and antigenically. In addition, outcome of chronic Chagas disease appeared to show marked regional variation (Miles 1979).

In the 1970s, isoenzyme electrophoresis began to be applied to study the genetic diversity and population genetics of trypanosomatids (Figure 6). Isoenzyme profiles of *T. cruzi* isolates from domestic and silvatic transmission cycles in a single endemic locality (Sao Felipe, Brazil) showed that domestic and silvatic strains were very different phenotypically and, by implication, genotypically. Thus, more enzyme characters separated these *T. cruzi* strains than distinguished species of *Leishmania*. *T. cruzi* isolates were subsequently characterized from many Latin American countries. Analysis of isoenzyme profiles confirmed the extensive diversity within the species, and initially indicated that there were three main strain groups, which were named principal zymodemes Z1, Z2 and Z3 (Miles 1983). Z1 appeared to be associated with marsupials, especially the genus *Didelphis* and Z3 with the armadillo, *Dasypus novemcinctus*. Host associations for Z2 were less obvious but may be linked to caviamorph rodents in the silvatic cycle in Bolivia, from which *Triatoma infestans* was proposed to have spread to the six southern cone countries of South America (i.e. Argentina, Bolivia, Brazil, Chile, Paraguay, Uruguay) and to southern Peru. The zymodeme concept contributed to the description of *T. cruzi* transmission cycles as:

- non-overlapping or discontinuous, as in Sao Felipe where distinct *T. cruzi* strains were transmitted by domestic bugs (Z2, *Panstrongylus megistus*) and silvatic bugs (Z1, *Triatoma tibiamaculata*)
- overlapping or continuous, as in Venezuela where the same principal zymodeme (Z1) was believed to be transmitted by a single bug species (*Rhodnius prolixus*) considered to be common to domestic and silvatic transmission cycles
- enzootic, as in the Amazon basin and the USA where triatomine bugs do not colonize houses and silvatic *T. cruzi* strains rarely caused human infection (Miles 1979).

One reason for such interest in the heterogeneity of *T. cruzi* is to assess whether different strains are responsible for the diverse clinical outcomes of Chagas disease. The high prevalence of *T. cruzi* Z1 in the north of South America, where mega-esophagus and megacolon are rare, and the abundance of Z2 in central and eastern Brazil, where megasyndromes are common, suggested that some *T. cruzi* strains were more likely to cause chronic Chagas disease (Miles et al. 1981c). Both Z1 and Z2 have, however, been isolated from symptomatic acute phase infections and both can recrudesce after unsuccessful treatment (Luquetti et al. 1986). Although only Z2 was isolated by the same authors from symptomatic chronic Chagas disease, there is no proof that Z1 was not (also) present earlier in the infection and responsible, at least in part, for the poor prognosis. Mixed zymodeme infections have been reported from both mammalian hosts and triatomine bugs.

Identification of *T. cruzi* strains by isoenzyme profiles led to selection of biological clones representing different epidemiologies in Latin America for use as reference strains in experimental studies (together with some traditional uncloned laboratory strains). The

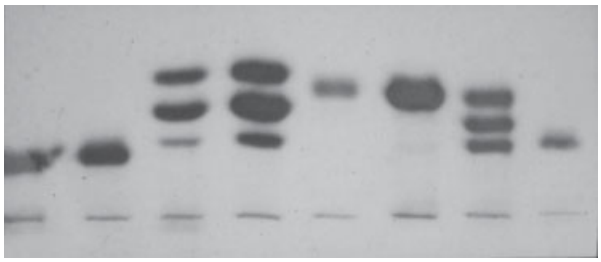

Figure 6 *Isoenzyme profiles of* Trypanosoma cruzi *isolates by starch-gel electrophoresis*

World Health Organization *Trypanosoma cruzi* reference strains are as follows (* = derived from clonal populations):

- M/HOM/PE/00/Peru
- M/HOM/BR/00/12 SF
- M/HOM/CO/00/Colombia
- M/HOM/BR/00/Y strain
- M/HOM/BR/00/CL strain

- I/INF/PY/81/P63 CL*

The use of reference strains encouraged detailed characterization by other methods, particularly by Dvorak and his collaborators (Dvorak 1984). It was found that clones of different principal *T. cruzi* zymodemes differed radically in DNA content, in kinetoplast DNA minicircle fragment patterns (schizodemes), in elemental composition of iron, zinc, and potassium, in oxidative metabolism, in antigenic profiles, in extracellular and intracellular growth rates in vitro, in virulence and tropism in experimental animals, and in response to experimental chemotherapy (Nozaki and Dvorak 1993). There is broad agreement between the zymodeme and schizodeme groupings and a correlation with abundance of a particular surface antigen (Carreno et al. 1987; Chapman et al. 1984). Polymerase chain reaction (PCR)-based analyses of polymorphisms in ribosomal RNA genes and in mini-exon genes have confirmed the presence of at least two major lineages, one that corresponds with Z1 and a second that incorporates Z2 (see below) (Stothard et al. 1998). Functional analysis of gene promoters also partitions *T. cruzi* into two major groups (Nunes et al. 1997).

Tibayrenc and colleagues subdivided the Z1, Z2 groups into many zymodemes, performed extensive further studies on their distribution in South America and elaborated a 'clonal hypothesis' which proposes that distinct *T. cruzi* clones are propagated asexually and largely disseminated separately (Tibayrenc et al. 1993; Brisse et al. 2000). PCR has been used to isolate kinetoplast DNA probes specific to widespread 'major clones' of *T. cruzi*. Most allozyme frequencies and measures of linkage disequilibrium have supported clonal propagation, and accord with single or small number of bugs invading houses and introducing a restricted number of populations of *T. cruzi*. Still further methods, including microsatellite analysis (Macedo et al. 2001) confirmed the broad validity of the principal subdivisions of *T. cruzi*.

The two major subdivisions of *T. cruzi* have now been named by international consensus as *T. cruzi* I (Z1) and *T. cruzi* II (incorporating Z2) (Anon. 1999). It has been proposed that *T. cruzi* I evolved in an arboreal palm-tree habitat with the triatomine tribe Rhodniini, in association with the opossum *Didelphis* (Gaunt and Miles 2000, 2002). *T. cruzi* II may have evolved in a terrestrial habitat with the triatomine tribe Triatomini, in association with edentates or ground-dwelling marsupials or, alternatively, by more recent host transfer of *T. cruzi* I into primates (Fernandes et al. 1999; Gaunt and Miles 2000). *T. cruzi* II has been further divided by into five subgroups, *T. cruzi* IIa–e, all previously recognized by isoenzyme profiles, and of which *T. cruzi* IIa corresponds with Z3 (Miles et al. 2003a). The affinities of *T. cruzi* IIa (Z3), whether with *T. cruzi* I or *T. cruzi* II, are still somewhat controversial (Brisse et al. 2000; Robello et al. 2000; Sturm et al. 2003; Campbell et al. 2004).

Contemporary studies of allozyme frequencies in African trypanosomes suggested the presence of genetic exchange in what hitherto had been assumed to be an asexual organism. Although the genetic mechanisms are not fully understood, experimental crosses with drug-resistance markers have shown that *T. brucei* undergoes recombination in the tsetse fly vector, probably in the salivary glands. Genetic exchange in *T. cruzi* is most likely to occur, as with African trypanosomes, among undisturbed silvatic cycles of transmission. Allozymes of phosphoglucomutase (PGM) for silvatic isolates of *T. cruzi* from the Amazon basin suggested occurrence of sympatric hybrid and parental strains. This is in accord with random amplification of polymorphic DNA (RAPD), which shows sharing of fragments between putative hybrids and one or other of the putative parents (Carrasco et al. 1996). Further evidence of genetic recombination has come from restriction fragment length polymorphisms (RFLP) studies with gene probes for three *T. cruzi* enzyme genes, and suggests that homozygote and heterozygote loci for these genes occur sympatrically among clinical isolates (Bogliolo et al. 1996).

The presence of an extant capacity of genetic exchange in *T. cruzi* has recently been proven by the production of hybrid clones in the laboratory (Gaunt et al. 2003). Two biological clones of *T. cruzi*, from silvatic transmission in the Amazon basin (Carrasco et al. 1996), were transfected to carry different drug-resistant markers and then passaged through the entire life cycle. Six double-drug-resistant progeny clones were recovered from the mammalian stage of the life cycle. The progeny clones were analyzed by isoenzyme, karyotype, RAPD and microsatellite markers and by sequencing of nuclear

and maxicircle DNA targets. The progeny showed fusion of parental genotypes, loss of alleles, apparent uniparental inheritance of maxicircle kDNA and evidence of homologous recombination, although the frequency and precise mechanisms of recombination have not been determined. There were strong genetic parallels between the experimental hybrids and the genotypes among natural isolates of *T. cruzi*. These data (Gaunt et al. 2003) and independent phylogenetic evidence (Machado and Ayala 2001) suggest that *T. cruzi* IId and IIe are hybrid strains, in accord with earlier isoenzyme profiles, and that they are derived from strains similar to *T. cruzi* IIb and IIc. Thus *T. cruzi* IId and IIe haplotypes are split across the IIb and IIc phylogenetic clades. Sequencing of intergenic targets further suggests that *T. cruzi* IIa and IIc may also have some hybrid characters, with *T. cruzi* I and *T. cruzi* IIb being less complicated lineages (Sturm et al. 2003; Campbell et al. 2004). The CL Brewer strain selected for the genome sequence project (www.TcruziDB.org), is a IIe hybrid, which complicates assembly of the sequence.

An absolute link between *T. cruzi* genotypes and clinical outcome of infection remains unproven, and few attempts have yet been made to examine the role of genotypic and phenotypic diversity of the human host in influencing clinical prognosis (Campbell et al. 2004). Multiple human genetic markers can now be used to compare genetic susceptibilities to chronic Chagas disease, although this may have little direct impact on Chagas disease control (Fae et al. 2000). In support of the hypothesis that severity of outcome is determined by the infecting *T. cruzi* strain, Di Noia et al. (2002) report that serological recognition of the *T. cruzi* II specific epitope of a GPI-anchored mucin-like protein is associated with chronic Chagas disease. However, this is not surprising as the sera examined were entirely from the southern cone region of South America, where *T. cruzi* II appears to be overwhelmingly predominant in human populations. Nevertheless, using individual kinetoplast DNA signatures, it has been shown that genetically diverse *T. cruzi* populations may occur in tissues of the same patient, and with a differential distribution between heart and esophagus (Vago et al. 2000).

CLINICAL ASPECTS

Shortly after his pioneering discoveries, Carlos Chagas was once described as a man who searched for diseases that did not exist. Initial acute phase Chagas disease is not frequently noted and is easily confused with other clinical conditions: if present, acute symptoms usually subside within 2 months of their appearance. Patients in certain geographical regions may suffer mega-esophagus and/or megacolon, usually with associated heart disease, but abnormalities in the elecrocardiograph (ECG) and myocardiopathy of chronic Chagas disease may also be mistaken for other forms of heart problem. At least one-third of the 12 million or so people thought to be infected with *T. cruzi* and surviving the initial stage of infection appear to be clinically compromised.

Clinical manifestations

The initial phase of *T. cruzi* infection may lack specific signs and symptoms. In some cases, there is a lesion at the entry portal of the organism, giving rise, in the case of entry through the skin, to a cutaneous chagoma. If metacyclic trypomastigotes cross the conjunctiva, the resultant painless but inflamed, periopthalmic, unilateral edema and conjunctivitis is known as Romana's sign (Figure 7). There may be local infiltration of lymphocytes and monocytes, and regional lymphadenopathy adjacent to these lesions. Rarely, multiple chagomas have been described during acute infections in infants. Acute infections are more common and more severe in children. Less than 10 percent of children die during the acute stage. General clinical changes at this stage may include fever, hepatosplenomegaly, generalized lymphadenopathy, facial or generalized edema, rash, vomiting, diarrhea, and anorexia. Early ECG changes may be sinus tachycardia, increased P–R interval, T-wave changes, and low QRS voltage, and death may be due to

Figure 7 *Romana's sign*

acute myocarditis. Meningoencephalitis is infrequent, mainly found in infants and carries a very poor prognosis. In patients suffering recrudescent *T. cruzi* infection associated with acquired immune deficiency syndrome (AIDS), the organism commonly crosses the blood–brain barrier and causes fatal meningoencephalitis (WHO 2002).

Incubation period may be as short as 2 weeks, or several months if infection is acquired by blood transfusion. Prolonged incubation period in recipients given contaminated blood is thought to be due to the poor capacity of circulating broad blood forms to invade cells. Splenomegaly and general lymphadenopathy are frequent in such cases.

In a small proportion of seropositive mothers, *T. cruzi* crosses the placenta, giving rise to abortion or premature birth. Hepatosplenomegaly is common in congenital infections and there may be fever, edema, metastatic chagomas, and neurological signs, such as convulsions, tremors, weak reflexes, and apnea. Signs of cardiac involvement are rare; ECG is usually unchanged but can show low voltage complexes, decreased T-wave height, and increased atrioventricular (AV) conduction time. Premature birth associated with congenital Chagas disease carries a poor prognosis: symptoms are generally less severe if birth is not premature (WHO 2002).

Patients surviving the acute infection enter the indeterminate phase, in which there are no symptoms or signs of Chagas disease. Around 30 percent of these patients, however, develop chronic disease in which cardiac changes are most common, with arrhythmias, palpitations, chest pain, edema, dizziness, syncope, and dyspnea. The most frequent ECG abnormalities are right bundle branch block (RBBB) and left anterior hemiblock (LAH) but there may also be AV conduction abnormalities, sometimes complete AV block. Many different arrhythmias may occur including sinus bradycardia, sinoatrial block, ventricular tachycardia, primary T-wave changes, and abnormal Q-waves. Enlargement of the heart may be seen by chest radiography. Complications include embolism. Death is often sudden (WHO 2002).

The regions of the alimentary tract most often affected in the digestive form of chronic Chagas disease are the esophagus and colon, with loss of peristalsis, regurgitation and dysphagia, or severe constipation, fecaloma, and progressive dilatation of these organs.

Further details of clinical aspects of chagasic heart disease, mega-esophagus and megacolon can be found in a PAHO Expert Committee Report (PAHO 1994).

IMMUNOLOGY

In view of the intense interest in the immune response to *T. cruzi* infection, it is surprising how little is understood about either the protective mechanisms or the autoimmune involvement in the pathogenesis of Chagas disease. Individuals surviving acute infection are able to mount an immune response that suppresses parasitemia but is unable to eradicate infection. In the absence of specific treatment, infection is normally maintained for life. *T. cruzi*-specific antibodies may be detectable within the first 2 weeks, and seropositivity usually remains throughout life in untreated patients. All immunoglobulin (Ig) subclasses are elevated. IgM titers rise early, with increased concentrations, followed by rising IgG titers. Unlike African trypanosomiasis, in which antigenic variation stimulates a sustained increase in IgM, in Chagas disease IgM levels fall as the acute infection subsides. As anticipated for an organism dividing intracellularly, the suppressive immune response also involves cell-mediated immunity. Partial protection by artificial immunization with purified antigens in mice has been shown to be T-cell dependent (Wrightsman et al. 2002).

Numerous studies have been performed on the immune response to *T. cruzi* infection in mice, recently aided by transgenic mouse technology, which allows the course of infection to be observed in knockout mice that are deficient in particular components of the immune response (Tarleton et al. 2000). Hypergammaglobulinemia (of IgG2a, IgM, IgE) persists in mice until 13 weeks post infection and then IgG2a and IgM levels fall. Although mouse strains vary considerably in their antibody response and resistance to *T. cruzi*, IgG1, IgG2a, IgG2b and IgM titers are sustained throughout infection, possibly with a more dominant IgG2b isotope response in a resistant strain of mouse (Rowland et al. 1992). During the acute phase of infection in mice, production of the cytokine interleukin (IL)-2 is severely suppressed, possibly by repression of transcription of the IL-2 gene. Killing in macrophages is dependent on production of interferon-gamma (INF-γ), synergistic with tumor necrosis factor-alpha (TNF-α), triggering macrophage activation, and nitric oxide production (Silva et al. 1995). Nevertheless, studies in mice suggest that *T. cruzi* infection does not necessarily lead to a dominance of T helper (Th)1 patterns of cytokine production. Th1 cells may be a requirement of immunological control of infection and Th2 cells may contribute to parasite persistence and severity of disease (Kumar and Tarleton 2001).

It is not clear how *T. cruzi* survives for life in the infected mammalian host. Immunohistochemical staining suggests that *T. cruzi* antigen can be detected in chronic, chagasic cardiomyopathy, indicating that residual pseudocysts are present. *T. cruzi* amastigotes could be found at autopsy in the hearts of 84 of 556 patients with diffuse, chronic, chagasic myocarditis (Brener 1994). Nests of *T. cruzi* have also been found in the smooth muscle cells of the central vein of the adrenal gland at autopsy in around 50 percent of patients with chronic Chagas disease (Teixeira et al. 1997). Several methods have been proposed by which *T. cruzi* escapes action of antibody, including binding of the third component of

complement by a specific trypomastigote surface glycoprotein to inhibit activation of the alternative complement pathway and binding of human C4b to restrict the classical pathway (Beucher et al. 2003). The histopathological picture in chronic Chagas disease suggests some autoimmune involvement: antibodies to host epitopes on specific proteins such as myosin and ribosomal P proteins have been reported.

PATHOLOGY

The pathology at the portal of entry is similar whether the chagoma is cutaneous or a Romana's sign, with infiltration of predominantly lymphocytes and monocytes. In the heart, no inflammatory response is said to be directed towards unruptured pseudocysts, but rupture is followed by infiltration of lymphocytes, monocytes and/or polymorphonuclear cells. The degree of parasitism is highly variable in clinical cases and in experimental infections in mice – in the latter, it is dependent on strain of infective organism and strain of mouse (Marinho et al. 2004; Risso et al. 2004). In congenital Chagas disease, amastigotes may be very widespread but are most common in cardiac and skeletal muscle or reticuloendothelial cells. If there is meningoencephalitis, parasites can be found in perivascular spaces or in glial and neuronal cells with an histopathology typical of acute meningoencephalitis (WHO 2002).

In patients surviving the acute infection, the inflammatory response in the heart subsides. Two principal forms of pathology have been described in chronic Chagas disease. In the first or neurogenic form, the heart remains free from any progressive myocarditis, but focal lesions are found in the conducting system of the heart and there is a loss of ganglion cells, particularly from the parasympathetic nervous system. Experimental studies in dogs, in which focal cardiac lesions have been reconstructed from histology of tissue sections taken at autopsy, show a good correlation between ECG abnormalities and histopathology. Longitudinal studies of ECG abnormalities in patients with chronic chagasic heart disease followed up by postmortem histology show a similar correlation between ECG abnormalities and lesions of the conducting system. The right bundle branch is found to be most frequently affected, consistent with the frequency of RBBB in chronic Chagas disease. The left conducting system is considered to be less vulnerable to focal lesions because of its more diffuse or bifascicular course. In a proportion of patients, the inflammatory response appears to be reactivated resulting in a renewed myogenic form of chronic Chagas disease and a progressive myocarditis with more diffuse lesions, a slower decline in cardiac function, and less sudden death. Lymphocytes and macrophages infiltrate the heart and mycocardial fibers are replaced by interstitial fibrosis (Brener and Andrade 1979).

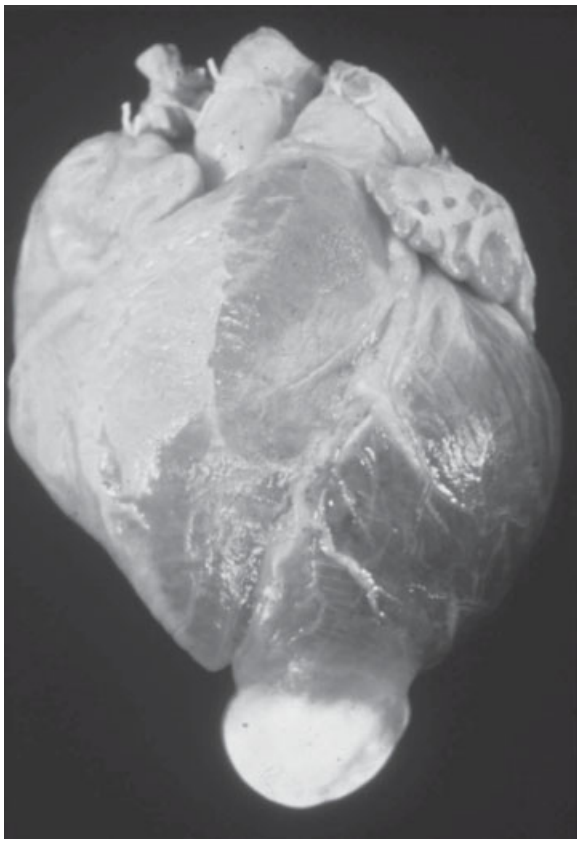

Figure 8 *Apical aneurysm of the left ventricle (Courtesy of Dr J.S. de Oliveira)*

At the gross level, the heart may be enlarged (megacardia) with focal thinning of the myocardium, which may be particularly frequent and pronounced at the apex of the left ventricle, in the form of an apical aneurysm (Figure 8). The presence of apical aneurysm is considered to be a pathognomonic sign of chronic chagasic heart disease. Of the intestinal sequelae chagasic mega-esophagus (Figure 9) is generally more common than chagasic megacolon (Figure 10); both may occur in the same individual and each is frequently associated with chagasic cardiopathy. A moderate or severe inflammatory response may be seen in the smooth muscle of the esophagus or colon and in the myenteric or Auerbach plexus during acute infection; in chronic Chagas disease the inflammatory response in these organs is usually mild.

Qualitative observations of neurological damage in Chagas disease were recorded as early as the 1930s. Köberle and his colleagues made painstaking quantitative studies of the number of ganglion cells present in normal and chagasic sections of heart, esophagus, and colon, and demonstrated widespread and significant ganglion cell loss, especially from the parasympathetic autonomic system (Köberle 1974). Neuron loss was found in many different organs but was most frequent in the heart and alimentary tract. The variable onset of

Figure 9 *Mega-esophagus:* **(a)** *postmortem;* **(b)** *on radiograph (Courtesy of Dr J.S. de Oliveira)*

ECG abnormalities, mega-esophagus and megacolon was understandable in terms of age-related neuron loss exacerbating the neurological damage attributable to *T. cruzi* infection. In addition, it was proposed that different hollow organs varied in the degree to which they could tolerate neuron loss; beyond these organ-specific thresholds, functional abnormalities and dilatation would begin to appear. Several authors have confirmed neuron cell loss in chronic Chagas disease (Lázzari 1994) and experimental studies in animals have shown that this neurological damage can occur early in the acute infection. Thus, the extent of *T. cruzi* infection in the acute phase and concomitant neurological damage may govern long-term prognosis, at least as far as the neurogenic form of chronic Chagas disease is concerned. Although some nerve cells may be parasitized, it is generally considered that ganglion cells are not destroyed as a direct result of parasitism. Early ganglion cell destruction led Köberle to the conclusion that a neurotoxin was produced by *T. cruzi*. Subsequent studies in experimental animals, however, have showed adsorption of *T. cruzi* antigens to uninfected tissue following pseudocyst rupture, with the implication that a T cell-mediated immune response could give rise to focal destruction of uninfected cells. Some of the physiopathological signs of chronic Chagas disease are compatible with dominance of the sympathetic system, predictable if the parasympathetic system is more exposed to damage from *T. cruzi* infection. Indeed, Oliveira demonstrated that the pathognomonic sign of apical aneurysm could be induced in rats, in the absence of *T. cruzi* infection, by inoculation of catecholamines (Oliveira 1969; Lázzari 1994). A sympathetic dominance is also apparently associated with sudden heart failure. Histochemical quantification of sympathetic and parasympathetic innervation has shown more severe parasympathetic denervation (Machado et al. 2000).

The trigger that leads some patients to the renewed inflammatory response and progressive decline of chronic myogenic Chagas disease is not clear, but the histopathological picture is suggestive of an autoimmune process. Release of sequestered antigens by destruction of normal cells to which *T. cruzi* antigens are adsorbed could lead to an autoimmune pathology with an unpredictable onset. Much research has been done in an attempt to elucidate the autoimmune pathogenesis of chronic Chagas disease. It seems clear that autoantibodies appear in experimental animals later than significant neuron destruction. Monoclonal antibodies to rat ganglia cross-react with *T. cruzi*; conversely, some monoclonal antibodies raised to *T. cruzi* cross-react with mammalian tissues. Numerous tissue cross-reactive antibodies have also been reported from patients with chronic Chagas disease. A possible candidate for a cross-reactive epitope between *T. cruzi* and normal host components is the C-terminus of the *T. cruzi* ribosomal P protein (Mahler et al. 2001). IgG fractions of chagasic sera contain antibodies to a motif shared by the C-term-

Figure 10 *Megacolon (Courtesy of Dr J.S. de Oliveira)*

inal region of the P0 ribosomal protein, the β_1-adrenoreceptor and the M_2 muscarinic receptor, yet are absent from control sera, and antibodies affinity-purified from chagasic sera modulated receptor function (Chiale et al. 2001). Putative cross-reactive epitopes have been described from mammalian proteins such as myosin: recognition of *T. cruzi* B-13 protein antigen and a corresponding epitope in human myosin heavy chain is said to be associated with chronic chagasic cardiopathy (Cunha-Neto and Kalil 2001). Several attempts have been made to implicate cell-mediated autoimmune pathology by studies in vitro, or by adoptive transfer of immunopathology with cells from infected donors to naive recipients: granulomata around the sciatic nerve have been induced experimentally by cell transfer and newborn syngeneic grafts were rejected by *T. cruzi* infected mice, but not by control mice (Ribeiro dos Santos et al. 1992). The CD4 T cell-dependent transplantation model of syngeneic mouse hearts grafted onto chronic chagasic recipients has suggested that anti-laminin antibodies might be used to suppress the process of autoimmune rejection (Silva-Barbosa and Savino 2000). In contrast, there is chronic persistence of the parasite (Schijman et al. 2004), and survival of syngeneic heart transplants in mice, with no signs of autoimmune rejection in the absence of direct parasitization of heart tissue (Zhang and Tarleton 1999; Tarleton 2001).

The pathogenesis of Chagas disease remains far from understood. A tenuous unifying hypothesis emerges from these diverse considerations: in the acute phase, neuron loss is precipitated by destruction of normal cells that have adsorbed *T. cruzi* antigens, which, dependent on the degree and extent of damage, is followed by a benign or catastrophic neurogenic clinical outcome; a relapse with progressive inflammation, and putative cell-mediated autoimmune involvement, occurs in an unfortunate minority of patients. Girones and Fresno (2003) review evidence for autoimmunity in chronic Chagas cardiomyopathy.

For a review in English of Chagas disease and the nervous system, see PAHO (1994); for an authoritative review on pathogenesis, see Lopes and Chapadeiro (2004).

DIAGNOSIS

In some acute *T. cruzi* infections, trypanosomes may be found transiently in the peripheral blood by direct microscopy of unstained, wet blood films. More scanty parasitemias can be detected by microscopy of Giemsa-stained thick blood films or by microscopy after concentration of trypomastigotes from blood. Concentration methods include:

- hematocrit centrifugation (with caution to avoid tube breakage and exposure to infection) followed by searching for trypomastigotes in or immediately above the Buffy coat layer
- allowing the blood to coagulate and searching for trypomastigotes in centrifuged serum (Strout's method)
- lysis of red cells with 0.85 percent ammonium chloride and centrifugation to sediment trypomastigotes.

In the indeterminate and chronic phases of the infection, *T. cruzi* is present in such low numbers in the peripheral blood that parasitemia is not patent to microscopy even after the above concentration methods. Xenodiagnosis, in which colony-bred uninfected triatomine bugs are fed on a suspect host and dissected about 20–25 days later to detect epimastigotes, or blood culture, are employed for parasitological diagnosis of chronic infections. Xenodiagnosis is generally favored for routine use in Latin America because, unlike blood culture, it does not require stringent aseptic precautions. Colonies of triatomine bugs are usually maintained by feeding on chicken blood, as birds are not susceptible to *T. cruzi* infection. If *T. infestans* is used, colonies must be examined periodically for presence of the monogenetic kinetoplastid *Blastocrithidia triatomae* as this may be confused with *T. cruzi* when bugs are dissected. Triatomine nymphs can survive for several months

without feeding and xenodiagnosis may thus be used in rural locations, as long as the bugs are protected from high temperatures. It is advisable to use a local species of domestic vector; *R. prolixus* and *T. infestans* are favored, *R. prolixus* feeds most avidly but may give rise to hypersensitivity skin reactions in individuals sensitized to bug bites. Precautions must be taken in dissecting infected bugs to avoid exposure to infection. Sterile diluents for bug feces should be used so that results are not confused by motile contaminants, such as ciliates. Under ideal conditions, blood culture on to a blood agar base with physiological saline overlay can be as sensitive as xenodiagnosis; cultures are inoculated 'through the cap' to minimize contamination (Miles 1993).

In central and northern South America *T. cruzi* must be distinguished from nonpathogenic *T. rangeli*, although in practice *T. rangeli* is almost never seen in human blood. *T. rangeli* and *T. cruzi* can both multiply in bugs used for xenodiagnosis. Long epimastigote forms with a small kinetoplast and pointed posterior end indicate the presence of *T. rangeli*, but such forms are not always present. In a proportion of infected bugs *T. rangeli* infections will progress to hemolymph and salivary gland infections (Hoare 1972).

Detection of parasite DNA is theoretically an attractive alternative to demonstration of the whole organism. PCR protocols have been developed that can show the presence of *T. cruzi* infection in the chronic phase. Although extremely sensitive after DNA extraction of blood samples, the PCR approach is not yet simple enough for routine diagnosis. In the long term, if adaptable to a low-cost rapid assay, PCR might be applicable to screening of transfusion blood or monitoring the success of chemotherapy (Castro et al. 2002).

In principle, serology detects exposure to infection rather than an active infection. In *T. cruzi* infection, however, both the infection and seropositivity are generally maintained for life unless specific antiparasite chemotherapy has been given. Only rarely have untreated individuals become seronegative (and presumably lost their infections). A sensitive and specific complement fixation text (CFT) was developed in 1913, but is now rarely used due to its complexity. Favored serological tests are the indirect fluorescent antibody test (IFAT), the enzyme linked immunosorbent assay (ELISA) and the indirect hemagglutination test (IHAT). Care is required with the IFAT to exclude nonspecific antibody binding (usually by selecting a high cut-off serum dilution between positive and negative sera, such as 1 in 80 or above). The ELISA requires careful standardization of conjugate batches, duplicate test wells, and positive and negative serum controls should be run on every plate. The IHAT is commercially available and convenient but said to be somewhat less sensitive than IFAT or ELISA, which is also commercially available (Oelemann et al. 1998). Serum or blood spots collected on filter paper can be used as the source of antibodies but serum provides a more accurate estimate of antibody titer. Cross-reactions may occur with other infectious diseases, notably visceral leishmaniasis and cutaneous leishmaniasis, which may be sympatric with Chagas disease. The advent of recombinant DNA technology has led to the testing of a series of *T. cruzi*-specific proteins selected from expression libraries (Umezawa et al. 2003). Detection of IgM antibodies (with IgM-specific conjugates) in newborn infants suspected of Chagas disease provides a means of helping to distinguish congenital infection from trans-placental transfer of IgG from mother to child.

In all cases, and especially in travelers returning from Latin America, clinical background should be explored thoroughly for a history of exposure to triatomine bites, blood transfusion or other sources of infection. Parasitological diagnosis is usually performed only if serology is positive. *T. cruzi* is isolated from only about 50 percent of seropositive individuals by xenodiagnosis, with 20 or more triatomine bugs, or by blood culture. Some clinical signs, such as right bundle branch block (RBBB), may be pathognomonic or highly indicative if associated with a supportive history. Hirschsprung's megacolon is seldom confused with chagasic megacolon because the former is rare in adults; when necessary, electromanometry or radiography can help with the differential diagnosis (Miles 1994)

EPIDEMIOLOGY AND CONTROL

Chagas disease is essentially a public health problem that is sustained by poor housing and poverty. The later nymphal stages and adult triatomine bugs are quite large (adults of some species may be more than 4 cm long) and, although they are reclusive insects, bug infestation is a considerable nuisance to householders. Heavy bug infestations would not be tolerated if there were lesser economic and health burdens in the affected communities. It follows that economic development, access to insecticides, improved housing, and health education should interrupt vector-borne transmission of *T. cruzi*, and this has proven to be the case in several successful control campaigns (Wanderley 1993). This is, however, of little comfort to the 11 or 12 million people who are already infected with *T. cruzi*.

A single (unsatisfactory) drug is now readily available for the specific treatment of Chagas disease; access to it may be life-saving in the initial stage of infection. Yet acute cases are seldom seen and recognized, and it is still debated whether the continued presence of the organism in the chronic stage, or repeated infection in endemic areas, has an affect on the long-term prognosis, which might largely be dictated by the severity of early infection. Treatment of chronic cases thus relies on alleviation of symptoms either by drugs or by installation of pacemakers, or by elegant surgical procedures

that have been pioneered in Brazil. Although new drugs are highly desirable, their epidemiological impact depends on their ability to eradicate infection from the reservoir of humans already carrying *T. cruzi*: this demands drugs that are inexpensive and without side-effects (Urbina 2002).

The prospects for vaccination against *T. cruzi* are remote, even though immunization has been shown to protect animals against fatal, acute phase infections, and will remain remote until autoimmune involvement in pathogenesis is fully understood and can be excluded as a complication of the antigen administration. Thus, little research is directed towards vaccine development, and it is difficult to justify in the face of successful campaigns to eliminate domestic triatomine bugs.

Elimination of domestic bug populations is an attainable goal, although eradication of *T. cruzi* is beyond reach as it is a widespread zoonosis, with numerous silvatic reservoir and vector species. The distribution of human Chagas disease is somewhat enigmatic, and changing as both the spread of domestic vectors and destruction of forest vector habitats may lead to the emergence of new endemic areas. Much remains to be learned about the complexities of the epidemiology of Chagas disease in the context of parasite, vectors and reservoir hosts.

Epidemiology (including reservoir hosts)

The blood-sucking insect vectors of Chagas disease are a subfamily (Triatominae) of the Reduviidae in the order Hemiptera. Five tribes, 14 genera, and 130 species of triatomine have been described based on morphological characteristics (Lent and Wygodzinsky 1979; Carcavallo et al. 1997). Thirteen species occur in the Old World, and the remaining 105 are confined to the Americas. Seven of the 14 Old World species are related to *Triatoma rubrofasciata*, which occurs worldwide in ports with its host the rat (*Rattus rattus*), to which it transmits *Trypanosoma conorhini*; the remaining six Old World species are grouped into the unusual Indian genus *Linshcosteus* (Galvao et al. 2002).

Most New World triatomine species have silvatic ecotopes, such as palm trees, burrows, hollow trees, rock crevices or caves, where they feed from mammals, birds or reptiles, and many of the New World species have been reported as infected with *T. cruzi*. Five species, of three genera, have adapted to colonize domestic habitats and are responsible for abundant and widespread household infestations; they are: *Triatoma infestans*, *Rhodnius prolixus*, *Panstrongylus megistus*, *Triatoma brasiliensis*, and *Triatoma dimidiata*.

T. infestans is the main vector in the southern cone countries of South America (Argentina, Bolivia, Brazil, Chile, Paraguay, Uruguay) and in southern Peru; it is thought to have spread from the Cochabamba region of Bolivia, where it occurs in rocky silvatic ecotopes: outside Bolivia *T. infestans* is said to be restricted to domestic and peridomestic habitats. *R. prolixus* is the most important vector in northern countries of South America and in central America, with *T. dimidiata* a significant secondary vector. *P. megistus* occurs along the eastern seaboard of Brazil, which was formerly covered by a continuous zone of Atlantic forest, and in central-eastern Brazil. *T. brasiliensis* is the vector in the arid northeastern region of Brazil. *Triatoma sordida*, although extremely widespread in central and eastern South America and often described as an important domestic vector, is usually associated with chickens. Many other species are reported from houses but usually as small, infrequent colonies, or as adult bugs flying into houses attracted to light.

Triatomines are considered to be obligatory blood feeders; most species take mammalian or bird blood but some feed on reptiles. At least one genus (*Eratyrus*) is known to take blood also from large invertebrates that co-inhabit its natural hollow tree ecotope (Miles et al. 1981a). Each nymphal stage must take at least one bloodmeal before molting to the next. Bug pheromones in feces may lead to aggregation of vectors at feeding sites, such as roosting chickens. As there is no transovarial transmission of *T. cruzi*, older bugs are more likely to have fed from an infected host and are, therefore, more likely to be infected.

Adults of all species are winged, with the exception of the Chilean *Triatoma (Mepraia) spinolai*, which has wingless females and either winged or wingless males. Nevertheless, adult triatomines are not frequent flyers; they are almost never observed to fly in laboratory colonies unless artificially induced to do so, but may be seen flying in infested houses at dusk, particularly after heavy rain. Flight is known to be an important method of dispersion since adult bugs of some species commonly fly into houses. Adhesive eggs aid passive dispersion of *Rhodnius*, and nymphal stages can move from host to host by walking. The few natural predators and parasites of triatomines include wasps (*Telonomus*, *Gryon*) that develop in triatomine bug eggs, spiders, lizards, chickens, rodents and various other insectivores, parasitic nematodes, and fungi. Immunological analysis of insect food sources can be used both to determine sources of blood in bugs and to identify their natural predators by detecting ingested bug proteins. When alarmed some triatomines produce the distinctive smell of isobutyric acid, and make sounds by stridulation, in which the proboscis is rubbed in a ridged ventral groove. *Rhodnius* has climbing organs and can scale very smooth surfaces, possibly due to the need to climb smooth-trunked palms and palm-frond stems in its natural arboreal habitats. The distribution of domestic vector species within houses may reflect silvatic habitat preferences: thus *R. prolixus* heavily infests roofs made of palm fronds, and palm crowns are the principal

habitat of the genus; *P. megistus* is most frequently found in compressed mud and wooden framed walls, and its most frequent natural habitats are hollow trees or burrows among tree roots; *T. infestans* can be found in quite good quality housing living in the walls or among tiles at the edges of roofs.

More than 150 species of 24 families of mammals have been reported as infected with *T. cruzi*, and all mammal species are considered to be susceptible. Although birds and reptiles are insusceptible to *T. cruzi* infection, domestic chickens are extremely important epidemiologically because they sustain heavy triatomine bug infestations either at roosting sites inside houses, or in neighboring chicken houses, which may be overlooked during spraying campaigns. Important domestic hosts, apart from humans, are dogs, guinea pigs, cats, rats, mice, and any other mammals sleeping inside houses and closely associated with humans. Dogs are particularly important because of high prevalence rates of infection and as they are often abundant in endemic areas (Cohen and Gurtler 2001). Cats, although less frequently studied, also have high prevalence rates and possibly acquire infection via the oral route, by eating either triatomine bugs or house mice that have fed on them. Although smaller hosts, rodents may be abundant and provide an important source of infective bloodmeals. Pigs, goats, cattle, and equines usually have indirect contact with houses and very low prevalence rates of infection, although their enclosures may be infested with bugs.

The most ubiquitous silvatic reservoir host of *T. cruzi* is the opossum, *Didelphis*, which occurs throughout much of the range of *T. cruzi* in the Americas. Multiple nesting or resting sites of *Didelphis* encompass many types of triatomine habitat. High *T. cruzi* prevalence rates may be in part due to the fact that opossums will eat triatomines and might also transmit infection via anal gland secretions, in which infective metacyclic forms typical of the vector stage of the *T. cruzi* life cycle can occur. *Didelphis* also provides an important potential link between silvatic and domestic habitats as it occasionally nests around or inside houses. Edentates (armadillos and anteaters), especially the armadillo *Dasypus novemcinctus*, are commonly infected with *T. cruzi* and their epidemiological importance requires further investigation; they have contact with human households through hunting of armadillos and their consumption for food. *P. geniculatus*, a silvatic triatomine bug frequently found in armadillo burrows, is one species that is attracted to light and often flies into houses. Rodents are thought to have an important epidemiological role as in times of food scarcity or drought they might introduce triatomines and *T. cruzi* strains into new peridomestic nesting sites. Similarly, bats may roost in domestic habitats, encouraging triatomine infestation and bringing in *T. cruzi* strains. The numerous carnivore and primate species that may harbor *T. cruzi* have tenuous links with domestic transmission cycles.

Silvatic cycles of *T. cruzi* transmission extend approximately from southern Argentina and Chile (latitude 46°S) to northern California (latitude 42°N). Human infection is, however, much less widespread, from 44° 45′S in Argentina to the southern states of the USA. Prevalence estimates for human infection are based on rates of seropositivity (Miles 1982). National surveillance by serology indicates that Brazil has the largest number of infected individuals (about 5 million) in accordance with its land mass and population. Bolivia is reported to have the highest prevalence, with seropositivity rates of greater than 70 percent in some localities, and heavy *T. infestans* infestation of rural communities that are difficult to access. The World Health Organization has provided an outline of geographical distribution of *T. cruzi* infection within the affected countries (WHO 2002). As described above, endemic areas can be classed as having either separate domestic and silvatic transmission cycles, with separate vector species (e.g. eastern Brazil) or overlapping domestic and silvatic transmission cycles (e.g. parts of Venezuela and northern Brazil). Enzootic regions have rare human infections with sympatric (e.g. USA) and sometimes abundant (e.g. Amazon basin) silvatic transmission cycles (Miles et al. 1981a). Locally acquired Chagas disease is rare in the USA, partly because of higher living standards and better housing. Although bugs are occasionally found in and around houses with dogs (Beard et al. 2003) they infrequently attack humans, and transmission of *T. cruzi* is less likely as the local bug species tend to defecate after feeding. Occasionally adult bugs are attracted by light into camp sites. Silvatic bugs are widespread in the USA and *T. cruzi* infections are common in opossums, raccoons, and wood rats (*Neotoma*). Nevertheless, transmission might also rarely occur in the USA due to transfusion of blood from infected immigrant Latin American donors (Schmunis et al. 2001).

Around 300 autochthonous human *T. cruzi* infections have been reported from the vast forested Amazon basin, even though there are extensive roadside and riverine communities with houses ideally suited to colonization by triatomine bugs and *T. cruzi* infections abound among species of forest mammals. Tracing of trapped mammals to their nesting sites with a spool-and-line mammal-tracking device (Miles et al. 1981b) has helped to describe the ecotopes of silvatic triatomines, and show that the 13 known species of the central Amazon basin do not readily adapt to household infestation (Miles et al. 1981b). *R. brethesi*, which infests the piacaba palm (*Leopoldinia piacaba*), is reported to attack forest workers harvesting the palm fronds and sleeping nearby, some of whom acquire infection. *P. geniculatus*, normally associated with high humidity within armadillo burrows and difficult to adapt to laboratory colonies, has recently been reported infesting domestic pigsties in Pará state, Brazil and attacking the inhabitants of adjoining houses (Valente et al. 1998).

The destruction of natural habitats around houses in the Amazon may well encourage triatomine infestation, especially as wood and palm fronds are often used in house construction, inevitably bringing some silvatic vectors into houses (Coura et al. 2002).

Nonvectorial transmission of *T. cruzi* that is epidemiologically important includes transmission by blood transfusion, congenital transmission, and oral transmission. Where prevalence is high, seropositivity rates among blood donors may reach 20 percent (endemic localities in Brazil and Argentina) or even higher in Bolivia (60 percent) (WHO 2002). In large cities where there are many migrants from rural areas and many blood transfusions, a significant proportion of recipients will become infected in the absence of serological surveillance of donors or treatment of transfusion blood to destroy *T. cruzi*; there may be thousands of blood-borne infections each year. Control of blood-borne transmission is thus an essential part of campaigns directed primarily at the elimination of domestic triatomine bugs. In endemic areas where prevalence is high, many pregnant women will carry *T. cruzi*. Estimates vary widely but a low percentage (less than 5 percent) of infants born to seropositive mothers may acquire congenital infection (WHO 2002). If resources allow, serological screening of pregnant women, serological and parasitological follow-up of the newborn, and prompt chemotherapy of infected infants, can reduce mortality due to congenital infections (Blanco et al. 2000). Determination of rates of transplacental acquisition of infection are complicated by passive transfer of maternal IgG antibodies to *T. cruzi*, which may cause infants to be seropositive for several months after birth even in the absence of infection. There is convincing evidence of oral transmission and a high proportion of the few human cases in the Amazon basin are thought to have been acquired by this route (Coura et al. 2002). The most likely sources in such outbreaks are contamination of food with triatomine bugs, or with vector-like forms from opossum anal gland secretions, or through consumption of the uncooked meat or blood of an infected reservoir host. An increasing problem is the transfer of *T. cruzi* to organ recipients from infected donors, who must therefore be routinely screened for seropositivity. If already infected with *T. cruzi*, recipients risk a recrudescent acute phase infection in response to immunosuppression. Similarly, human immunodeficiency virus (HIV)-positive patients who develop AIDS may reactivate *T. cruzi* infection and develop meningoencephalitis (Lazo et al. 1998). *T. cruzi* infections in the immunocompromised will become epidemiologically more important as human migration to South American cities continues and urban HIV transmission spreads to rural areas that have endemic Chagas disease (de Gorgolas and Miles 1994).

TREATMENT

Chemotherapy

Two drugs have been used for specific chemotherapy of *T. cruzi* infection, nifurtimox and benznidazole (WHO 2002). Nifurtimox, a synthetic nitrofuran given by mouth and absorbed through the gastrointestinal tract, is no longer readily available. Dose rates employed were 8–10 mg per kg orally in three divided daily doses for 90 days, using tablets of 30, 20, or 250 mg. Higher doses of 15–20 mg per kg in four divided daily doses for the same period were recommended for infected children. Successful treatment thus required either hospitalization or careful monitoring to ensure compliance. Side-effects could include anorexia, nausea, vomiting, gastric pain, insomnia, headache, vertigo, excitability, myalgia, arthralgia, convulsions, and peripheral polyneuritis, and could lead to interruption of treatment. Nifurtimox is thought to act against *T. cruzi* by increasing oxidative stress through the production of free oxygen radicals. Benznidazole is a nitroimidazol which is also absorbed from the alimentary tract. Doses are 5–7 mg per kg orally in two divided doses for adults for 60 days with 100 mg tablets, and 10 mg per kg similarly for children. Adverse affects may include rashes, fever, nausea, peripheral polyneuritis, leukopenia, and, rarely, agranulocytosis. Benznidazole is thought to act by interaction of drug metabolites with DNA but not via oxidative stress.

Cure rates with both nifurtimox and benznidazole are not total and vary regionally. Suppression of parasitemia during acute infection may be life-saving and treatment is, therefore, recommended during the acute phase. The chronic phase is not always treated because the influence of persistent infection on long-term prognosis is uncertain, and there is a significant failure rate, such that up to half of patients may remain infected after treatment. Nevertheless, treatment is better tolerated in children, leading to the suggestion that, as well as acute cases, chronic cases in children might also always be treated (Estani et al. 1998). Treatment is essential for immunocompromised patients, especially if meningoencephalitis is present, in which case double or even higher dose rates may be recommended. Pre-emptive therapy has been described as safe and effective for preventing reactivation of *T. cruzi* infection during bone marrow transplantation (Dictar et al. 1998). In congenital cases, either drug has been used, nifurtimox at 8–25 mg per kg daily for 30 days and benznidazole at 5–10 mg per kg daily for 30–60 days (WHO 2002). Indicators of elimination of the parasite are negative xenodiagnosis together with, in acute cases, serological reversion within a year. However, negative parasitology is not sufficiently sensitive to prove absence of infection and, for chronic

cases, reversion of serology may take decades (Rassi and Luquetti 2003).

Allopurinol and itraconazole have been suggested as low cost, nontoxic alternatives for treatment of *T. cruzi* infection, but their efficacy is in doubt. Allopurinol, a structural analogue of hypoxanthine that is metabolized via the purine salvage pathway, prevents formation of ATP, and also interferes with protein synthesis by its incorporation into RNA. Experimental drugs thought to act against the enzyme sterol methyl transferase are under development, have shown promising activities in treatment of animal infection, and may proceed to clinical trial (Urbina 2002; Urbina et al. 2003).

Additional chemotherapy is an important part of supportive treatment in both acute and chronic Chagas disease (WHO 2002). Severe acute infections may require treatment for fever, vomiting, diarrhea, and convulsions; if heart failure is present, sodium intake is restricted; diuretics and digitalis may be recommended; anticonvulsants, sedatives, and intravenous mannitol may assist management of acute meningoencephalitis. Chronic chagasic heart disease may require treatment of heart failure through reduced activity, limitation of sodium, diuretics, vasodilation (angiotensin converting enzyme inhibitors), and maintenance of normal serum potassium; digitalis is only advisable as a last resort for treatment because it may aggravate arrhythmias by inducing premature ventricular beats or impeding AV conduction. A pacemaker may be required to manage bradycardia that does not respond well to atropine, or atrial fibrillation with a slow ventricular response in which vagolytic drugs are not effective, or complete AV block.

Life expectancy of patients with ventricular arrhythmias may be prolonged by treatment to prevent ventricular tachycardia or ventricular fibrillation: lidocaine, mexiletine, propafenone, flecainide, β-adrenoreceptor antagonists, and amiodarone are effective for treatment of ventricular extrasystoles; amiodarone is the most effective drug to treat arrhythmias, but in all cases drug treatment of arrhythmias may have an aggravating effect and patient management may be a complex combination of the use of drugs and a pacemaker. Lidocaine may be used intravenously in emergencies prior to drug administration orally. Surgical resection of arrhythmic endocardial regions may be considered, and surgical resection of ventricular aneurysms has been suggested but not extensively used. Expert reports (WHO 2002) and physicians who have specialized in management of Chagas disease should be consulted before case management can be embarked upon with confidence.

Surgical treatment

Elegant surgical procedures have been developed in Brazil to treat severe chagasic megacolon and mega-esophagus. Laxatives, colonic lavage or manual evacuation may be used to relieve symptoms of megacolon, with laparotomy if the fecaloma cannot be reached. Sigmoid volvulus can be relieved by decompressing intubation or surgery. Sigmoidostomy close to the rectosigmoid junction may simplify subsequent surgery to correct megacolon as it allows more of the colon to be retained.

Surgical treatment of megacolon is often based on the operation of Duhamel. The modified Duhamel–Haddad procedure consists of resection of the sigmoid loop, closing of the rectal stump and insertion of the descending colon through the rear wall of the rectum. The Haddad improvements introduced a two-stage operation, in which the lowered colon is first exteriorized through the retrorectal stump as a perineal colostomy and, secondly, with peridural anesthesia, the stump of the colon is sectioned into anterior and posterior halves, the anterior wall of the colon and posterior wall of the rectum held together in an inverted V, and then cut and sutured together to make a wide join between the colon and rectal stump (Figure 11). A series of 624 Duhamel–Haddad operations between 1966 and 1981 had an overall associated mortality of 6.6 percent (Moreira et al. 1985).

Mega-esophagus can be treated by dilatation of the cardiac sphincter or the Heller–Vasconcelos surgical procedure in which a portion of the muscle is removed from the junction of the esophagus and stomach without disturbing the muscular control of the wall of the stomach. More severe mega-esophagus may require partial removal of the distal esophagus and replacement with alternative portion of the alimentary tract such as jejunum. These and other surgical procedures are described in detail in the Brazilian literature (Raia 1983).

VACCINATION

Administration of crude *T. cruzi* lysates to experimental animals has been known for many years to suppress parasitemia, to prevent mortality from a subsequent

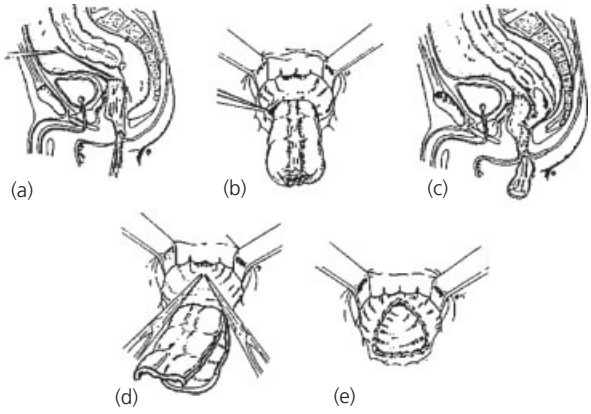

Figure 11 *The modified Duhamel–Haddad procedure for surgical correction of megacolon*

challenge infection, and yet not to prevent re-infection. 'Attenuated' *T. cruzi* strains have been used as experimental vaccines in human trials with small numbers of individuals, but organisms were not necessarily entirely non-infective, and are not known to have conferred resistance to infection (or superinfection). Various semi-purified or purified antigen preparations have similarly been shown in experimental models to confer protection against mortality on challenge but not to provide a sterile immunity (Taibi et al. 1993). An autoimmune response may have a role in the pathogenesis of Chagas disease, and this does not encourage research on candidate vaccines. Without a full understanding of the potential autoimmune involvement in pathogenesis it is difficult to envisage clinical trials of vaccines: subjects could not be given a live challenge, and would have to be followed for many years for the appearance of vaccine-induced pathology in the absence of infection. These aspects of Chagas disease suggest that resources would be most cost-effectively directed to further improvement of vector control campaigns rather than vaccine development. Immunotherapeutic modulation of progressive autoimmune damage in chronic Chagas disease has been proposed: if the intricacies of immune responses in the pathogenesis of Chagas disease can be convincingly unraveled, this may become possible for a small number of privileged patients.

INTEGRATED CONTROL

In 1948, successful trials of the organochlorine insecticide BHC for control of domestic triatomine bug infestation by Emmanuel Dias and Jose Pellegrino in Minas Gerais, Brazil, prompted their telegram to the Brazilian Ministry of Health suggesting that the end to vector-borne *T. cruzi* transmission was in sight (Miles 1996). The fundamental value of insecticides for control of triatomine bugs has never since been in doubt. Nevertheless, much research has been devoted to developing new methods of eliminating domestic triatomines, including the use of parasitic wasps, nematodes, and fungi; sophisticated traps for catching bugs; and juvenile hormones for preventing development of nymphal instars into adults. These alternative weapons have failed to have significant impact on vector populations.

A combination of insecticide spraying, health education or community participation and housing improvement has been the basis of successful national control programs, a superb example of which is the elimination of domestic *T. infestans* populations from São Paulo State in Brazil (Wanderley 1993). João Carlos Pinto Dias, the son of Emmanuel Dias, has led the elaboration of a systematic approach to triatomine bug control (Dias 1987).

- In the preparatory phase, all houses in the endemic area are mapped and sampled manually with flashlight and forceps for evidence of triatomine infestation: sampling may be assisted by spraying irritant pyrethroids on to suspect wall areas to dislodge bugs hiding in crevices. This mapping and sampling phase allows for the cost of insecticides, personnel, transport and equipment to be calculated, and for detailed planning of operations.
- In the attack phase, all houses and outbuildings are sprayed, irrespective of whether they are known to be bug infested. Failure to spray all infested domestic and peridomestic habitats may lead to rapid local re-emergence of bug populations. The entire spraying may be repeated during the next 3 months if live bugs can still be found in more than 5 percent of houses (except where there is heavy peridomestic infestation and a close link with adjacent silvatic cycles).
- In the vigilance phase, houses are sampled periodically through a surveillance system established with the local community and supported by health education. Thus, householders can report any residual infestation to a local volunteer who mobilizes an immediate insecticide spraying response. Simple surveillance kits consist of a sheet of paper pinned to walls suspected of infestation, and a plastic bag. Periodic examination of the paper may reveal either bug feces or bugs concealed between the paper and wall; the plastic bag is used by householders to collect any live bugs, with care to avoid contamination with bug feces. The vigilance phase is also supported by continuing contact with public health personnel. Although triatomines can sometimes be found in quite good quality housing, for example in tiled roofs (*T. infestans*) or in beds that are not regularly dismantled and cleaned, poor housing is most vulnerable to bug infestation. Encouraging and supporting the community to improve local housing, for example by plastering cracked walls, can contribute to the success of a control campaign. In houses infested by *R. prolixus* it is advisable to replace roofs of palm fronds by alternative materials.

In some localities, for example with domestic and silvatic *Triatoma brasiliensis* in northeastern Brazil, there may be heavy peridomestic infestation and a close link with silvatic habitats, such that rapid re-invasion can occur. In such cases, surveillance (rather than a complete respraying program of all houses and outhouses) may be implemented when the overall infestation rate is greater than 5 percent. Similarly, modification to control strategies, or measures to deal with silvatic foci, may be required at other sites with interaction between silvatic and domestic transmission cycles.

Early spraying campaigns used chlorinated hydrocarbons but their short residual activity (30–180 days) required repeated applications. Carbonates and organophosphates have also been used but the former are expensive and the latter are not well received by

communities because of their strong smell. Synthetic pyrethroids have been adopted for triatomine control since 1980 as they have a long residual activity and low toxicity, and several formulations are now available (Schofield 1994). Insecticide resistance (to dieldrin) is known only from small areas of Venezuela and has not interfered with control campaigns.

In 1991, an initiative was launched to use established triatomine control methods in a cooperative international campaign, referred to as the Southern Cone Programme, and designed to eliminate domestic *T. infestans* populations from the Argentina, Bolivia, Brazil, Chile, Paraguay, and Uruguay, with spraying of infested regions that spanned national frontiers intended to prevent re-infestation (Miles 1992). The strategy for this coordinated international program incorporated World Bank recommendations on the need for clear lines of responsibility, regional integration, and pragmatic local autonomy. The Southern Cone Programme has attracted new financial support and stimulated a vigorous and sustained effort. The overall cost of the programme is estimated to be a fraction of that of dealing with the burden of new cases of Chagas disease. An international review of the programme indicates a huge reduction in the geographical area infested by *T. infestans* and a determination to deal with those regions still affected. Miles et al. (2003b) summarize key features governing the success of the programme. Further intergovernmental control collaborations are being established in Central America, the Andean region and Mexico (Schofield and Dias 1998; Dias et al. 2002). Although the Amazon Basin is free of domestic bug populations, it is under threat from migration of species such as *T. infestans* and *R. prolixus* and from adaptation of local forest species to houses (Coura et al. 2002). A network of collaborating centers has recently been established to train local health workers in the recognition of triatomine bugs and acute cases of Chagas disease, and to plan responses to the appearance of domestic bug populations. In the past, lack of funds and poor continuity frequently interrupted control campaigns, in part because resources were diverted to resurgent malaria or outbreaks of dengue. It is essential that campaigns against different arthropod vectors are integrated, at both local and regional levels.

T. cruzi is one of several disease agents, including HIV infection, hepatitis, syphilis, and malaria, that can be transmitted by contaminated transfusion blood. Screening of donors is an essential component of control campaigns and in almost all South American countries serological testing is mandatory. Effective serological tests include the IFAT, which can be used to distinguish maternal transfer of IgG from IgM due to congenital infections, the ELISA, the IHAT, and the CFT, although the latter is now seldom used. A single standardized test may be adequate, but simultaneous use of two tests is often recommended, and some cross-reactions with diseases such as visceral leishmaniasis are inevitable. It has been shown that CFT, IFAT, IHAT, and ELISA can give comparable results. The IFAT has been employed in large scale surveys in Brazil; ELISA has distinct advantages for survey work as it is highly sensitive, relatively low cost, and does not require microscopy. In some countries, such as Chile, cross-reactions with leishmaniasis are not a problem as visceral and cutaneous leishmaniasis are not endemic. Rigorous internal and external quality control of assay performance are required with repetition of a proportion of tests in a central laboratory and in collaborating external laboratories. Sample collection and record systems must be highly efficient and integrated with spraying operations, health education, and community participation aspects of control. The importance of screening blood for HIV infection in major urban areas is likely to improve access to screening for *T. cruzi* infection. Where seropositive rates are very high, positive transfusion blood may be treated with 125 mg of crystal violet per 500 ml and the blood stored at 4°C for 24 hours to destroy trypomastigotes. Side-effects are blue coloration of mucosae and skin in recipients of blood treated with gentian violet.

Serology is a vital and highly effective method of monitoring the success of control programs. In its simplest form, success is demonstrable by zero serological incidence in children born after the initiation of intervention measures. Thus, for a 10-year campaign, 5 years and 10 years after the beginning of vector control no vector-borne infections should occur in children aged 0–5 and 0–10, respectively. Pre-school children and school children obtaining basic or primary and junior schooling (e.g. ages 1–12 years) provide the ideal populations for serological surveillance. Baseline serological data are useful but not essential to planning serological surveillance of control: if interventions are effective, no significant increase in prevalence of seropositivity should occur for any age group after the campaign begins.

Ideally, all children in populations possibly exposed to vector-borne transmission should be tested as serology is a sensitive independent aid for the detection of residual triatomine infestation. Thus, one seropositive case, if congenital transmission and blood transfusion transmission are excluded, may lead to the identification of a single house that has escaped elimination of bugs. In countries such as Chile, which have a relatively small population, good infrastructure, preschool rural health clinics, regional hospitals, demographic data that include individual identification codes, and clearly defined areas of disease transmission, it is feasible to monitor the entire population exposed to transmission. In other countries, such as Brazil, with a very large population in endemic areas, it may not be possible or appropriate to survey the entire population of preschool and school children. There are two obvious alternatives for selection of sub-populations: the first, on a random sample

basis, and the second, where effort is concentrated on highly endemic localities. The second alternative is preferred as only in areas with relatively high seroprevalence will a detectable number of the very young acquire infection. Baseline serological data are available for Bolivia, Brazil, Peru, Argentina, Paraguay, and Uruguay to allow such sentinel sites of high endemicity to be selected. It might also be appropriate to survey localities at the margins of endemic areas where explosive outbreaks of disease, transmission might occur in previously unexposed populations.

Social and economic development in Latin America should, in time, eliminate vector-borne and blood-borne transmission of *T. cruzi* as a major public health problem. *T. cruzi* will, however, remain as a widely distributed enzootic infection, with the threat of re-emergence and spread to new areas of human settlement. The burden of management of chronic disease will be a problem for several decades. Further research on immunological evasion and molecular pathogenesis might improve prognosis for those already infected, and a low-cost, nontoxic drug may help eliminate *T. cruzi* from the human reservoir of infection. It is debatable whether other aspects of advanced research will have a significant direct impact on the control of Chagas disease, but they will lead to a fuller understanding of the fascinating epidemiology and biology of trypanosomatid infections.
